The monograph by Dr. HUGO ROESLER *Clinical Roentgenology of the Cardiovascular System* was noticed in these columns on its first appearance in 1937, when we said that it bore the stamp of careful thought and personal observation and showed on every page the author's intense interest in his subject. A second edition has now been published by Charles C. Thomas of Springfield and Baltimore and is distributed in Britain by Baillière, Tindall and Cox at 41s. The steady progress in this field of medicine is reflected by the many additions to the text and to the bibliographies at the end of each section. Dr. Roesler expresses his acknowledgment for much help received from colleagues connected with Temple University Hospital and Medical School, Philadelphia.

A little slimmer than usual, and manufactured according to wartime rulings, the 1943 *Year Book of Pediatrics* (Chicago: The Year Book Publishers; \$3.00), edited by Prof. I. A. ABT with the collaboration of Prof. A. F. ABT, makes a welcome appearance. It summarizes available literature—and the qualifying adjective excludes apparently all French, Scandinavian, Dutch, Belgian, and German periodicals. Perhaps for this reason articles which have been published in England seem more numerous than usual this year. The annotations chosen are grouped in over twenty sections and there are 76 illustrations. A subject-index and an index to authors complete the volume. The editorial comments are succinct and valuable, and a high standard of critical writing characterizes the whole book. Those interested in the health of children as well as in disease problems, common and rare, will find much of interest in this popular annual.

It is possible for a doctor to get a wider view of a cross-section of conditions and different types of prisoner-of-war life than others who are destined to stay for long periods in one camp. *The Sun Stood Still*, by J. C. MUSTARDÉ (The Pilot Press; 8s. 6d.) describes the experiences of a doctor who has moved from various camps and hospitals in both North Africa and Italy, and has thus had a broad insight into what actually goes on in these places. It gives the impression of being a just and accurate account of what it really is like to be a prisoner of war, without undue exaggeration for propaganda reasons, or camouflage due to the typical British habit of understatement. It is interspersed by gems of poetry, simple

but none the less philosophically profound. The vein of humour which runs throughout makes it a pleasure to read. Dr. Mustardé has lifted the veil from prison-camp life in such a vivid and delicate manner that anyone who wishes to know how the other half lives can be strongly advised to read this book; but it is also of special value to those interested in prisoner-of-war problems.

## Preparations and Appliances

### A TRANSFUSION STANDARD

Dr. V. H. COOPER (Loughborough) writes:

The type of transfusion standard described and illustrated here has been used in the local hospital and may perhaps be worth noting.

This standard consists of a 1 in. x 1 in. wooden upright 5 ft. in length, with a hook screwed into the head, or if elaboration is required an angle bracket with a loop at the free end, as shown in the illustration (the photograph shows this type of bracket merely because some were available; they are a refinement, not a necessity). At the lower end of the upright are two holes through which run bolts with thread and wing nuts at one-half and bent distally in the form of a hook; these bolts are about 16 in. apart (see smaller photograph inset on the left).

By unscrewing the wing nuts the standard can be quickly slipped on the uprights of the hospital type of beds at any corner, top left or right for right or left arm, or bottom left or

right for left or right leg, and then the wing nuts are rescrewed to requisite tightness to fix the standard to the bed. The standard can be varied in height in different hospitals according to the minimum head-room present, so that should the standard be affixed to a trolley, in the event of a transfusion being given in some place other than in the ward—i.e., operating theatre—the apparatus does not foul doorways, etc., when the patient is moved about.

The advantages of this standard are: (1) Its cheapness, simplicity, and ease of making. (2) It can be used for either arms or legs, unlike wall fixtures. (3) Being near the limb it requires only a comparatively short length of tubing and there is consequently less tendency to kinking, etc. (4) It is stable and therefore cannot be overturned like some standards. (5) It is moved with the bed, and therefore cannulae are not so readily pulled from the vein; it is also more convenient for nursing. (6) It can be fixed to the theatre trolley and transfusion given in the leg while the operation is proceeding, so that on transit the level of the bottle and its relation to the patient are constant and a regular flow of fluid is maintained. (7) Unlike wall fixtures only a few are needed.

## BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MAY 27 1944

## PSYCHIATRY AND SOCIETY

The White Paper on medical services says little about mental health; but it is admittedly a skeleton, or (less ominously) a clothes-horse, waiting to be decked with the intimate detail of material which will display its whole significance to the large family that resides in our island home. Perhaps if it had been remembered that the total number of beds that has to be provided for the major sort of mental illness is comparable to the total number of beds provided for all other forms of illness put together the authors of the White Paper might have felt obliged to say more even at this stage; but perhaps they were comforted by the thought that these beds were held mainly under the jurisdiction of local authorities. In Scotland, however, the voluntary or Royal hospitals provide for no fewer than a fourth of the total number of mental invalids. It is perhaps in consequence of this unequalled voluntary effort that it is from Scotland, in the annual report by Prof. D. K. Henderson on the work of the Royal Edinburgh Mental Hospital, that there comes a plea that mental and nervous disorder should be given consideration equal to that accorded to physical ill-health. It is not without significance for the planning and the organization contemplated in the White Paper that Prof. Henderson's plea met with instant recognition in the columns of our contemporary the *Scotsman*. The coexistence within a compact community such as Edinburgh of autonomous bodies like the Royal Hospital and an independent and locally representative newspaper probably makes more readily for mutual appreciation than would be possible in a highly centralized organization, divided as it would have to be geographically in its general administration from most of the communities it was designed to serve. Personal contact is the great catalyst of progress.

Prof. Henderson, mindful that the mental hospital in-patient represents only a fraction of the field of psychiatric medicine, and that reliable estimates have placed the incidence of psychogenic illness as a whole at anywhere from a sixth to a third or more of all the ailments the family doctor meets in his daily round, looks further and sees that doctors with training in psychological medicine may be destined to play a part in furthering the stabilization and solidarity of the community. In this, the *Scotsman* suggests, he would be walking hand-in-hand with the politician—"no bad thing, as politicians exist who are less skilled in the appreciation of social behaviour and

emotional reactions than they might be." That this is so few will deny, but they will also be disposed to question the psychiatrist's qualifications for this ambitious and anxious role. His claim is based partly on the fact that he is predominantly concerned in his daily work not with the "manifest content," as he would call it, of what people say nor with the ostensible reasons for what they do, but with their underlying motives, which are often so very different from their professed intentions. How important this can be for politicians is lucidly shown in a recent book on the psychology of politics, in which Mr. James Burnham, using psychiatric principles, declares that the laws of political life cannot be discovered by an analysis which takes words and phrases, either spoken or written, at their face value. "Logical or rational man plays a relatively minor part in political or social change. Non-logical man, spurred by environmental changes, instinct, impulse, interest, is the usual social rule." The opposing, more orthodox, view "has conceived history as the rational attempts of men to achieve their goals."

It is a curious fact that until the advent of dynamic medical psychology, textbooks of "pure" psychology were almost devoid of information or even of speculation about human motives. Knowledge of this kind has until recent years been reserved for men of the world. There is no reason, however, to suppose that this worldly wisdom cannot be comprehended scientifically, and more exactly and usefully. The scientific study of motives, temperaments, and attitudes is the subject-matter of psychological medicine, which, beginning with the exaggerated and more easily detected processes of disease, is now, especially under the impact of war, coming to be concerned with the normal person and his aptness for special tasks, such as holding a commission or flying an aircraft; in brief, with "positive health" in the mental field, in the same way as general medicine is being stimulated in the maintenance of physical fitness.

The *Scotsman*, referring in particular to the psychiatry of politics, says with truth that "the undertaking of such a delicate social therapy and surgery will require an intellectual, a scientific, and a humanistic endowment, on the part of those engaged in such work, of a very high calibre." It is of the utmost importance, if psychiatry is to play its proper part in building up and maintaining the health of the community, that it should attract recruits from among those with the best brains and the soundest character in the medical profession. Special attention must therefore be paid to making a thorough training in psychiatry as readily available to the aspirant as are facilities for study in other branches of medicine. Such institutions as the Maudsley Hospital, the Tavistock Clinic, the Cassel Hospital, and the Burden Neurological Institute have already done much in this way. Prof. Henderson has long advocated the institution of psychiatric clinics in general hospitals in this country; and the opening, after a delay due to war exigencies, of the first *ad-hoc* psychiatric clinic in a general teaching hospital in this country, the York Clinic at Guy's Hospital, signalizes the beginning of an additional type of hospital provision that is needed for the training of the psychiatrists and the nurses of the future.

## TOXICITY OF THE DIAMIDINES

On March 4 we recorded evidence suggesting that the trigeminal anaesthesia which since 1916 has been attributed to trichlorethylene was really initiated by a decomposition product, dichloroacetylene. Now Sen Gupta<sup>1</sup> has described 17 cases of this condition arising among 104 patients with kala-azar who have been treated with 4:4'-diamidino-stilbene (stilbamidine). The symptoms complained of were sensory disturbances, dissociated anaesthesia, loss of light touch with preservation of the sense of pain and temperature, over parts of the area supplied by the trigeminal nerve. There were no nerve lesions elsewhere. The dissociated anaesthesia locates the lesion in the principal sensory nucleus of the fifth nerve situated in the pons. There is no evidence of any danger to life, and after the paresis is fully established the tendency is to a slow recovery. The symptoms mostly appeared insidiously three to four months after cessation of the treatment.

Hawking and Smiles<sup>2</sup> showed that stilbamidine when exposed to ultra-violet light gave a brilliant blue fluorescence which is visible down to dilutions of 1/1,000 million. By this method they established that the substance is absorbed in large quantities by living trypanosomes, and that in mice it is stored in the liver and kidneys. Henry and Grindley,<sup>3</sup> making use of this method, found that stilbamidine is absorbed by the red corpuscles. They also investigated the rate of excretion in two adult men. Each was given an injection of the drug, and the excretion was comparatively high in the first two samples of urine only. Then followed a diminishing rate of excretion until after two and a half days it became undetectable. The total amount of drug excreted over this period was only 10% of the amount injected. There is, therefore, no doubt that much of the drug is retained in the body; but the long latent period before the development of symptoms of trigeminal anaesthesia seems to suggest that these may be brought about by some decomposition product. There is certainly no obvious chemical relation between dichloroacetylene and a 4:4'-diamidino-stilbene; but that they or their derivatives have a selective toxic action on a localized part of the central nervous system suggests that there may be some association. This may be a similarity in the molecular structure of the actual toxic substance which has so far not been established for either drug. Dichloroacetylene is an extremely unstable compound, and its behaviour inside the body will require further investigation.

In 1938 King, Lourie, and Yorke<sup>4</sup> discovered that synthalin (decane diguanidine dihydrochloride) and related guanidines were actively trypanocidal, and later Ewins and his colleagues<sup>5</sup> isolated a series of aromatic diamidines, of which the two most useful have proved to be 4:4'-diamidino-stilbene (stilbamidine) and 4:4'-diamidino-diphenoxy-propane (propamidine). Stilbamidine has had an immediate cure rate of 98% in Indian kala-azar, and the proportion of cases relapsing after a single course of

treatment is very low. Thrower and Valentine<sup>6</sup> showed that, besides the action of these drugs in kala-azar and other protozoal diseases, propamidine possessed bacteriostatic and bactericidal activity against *Staph. aureus* and  $\beta$  haemolytic streptococcus. McIndoe,<sup>7</sup> Morley,<sup>8</sup> Kohn,<sup>9</sup> and Butler,<sup>10</sup> with their colleagues, have reported good results from its use in the treatment of wounds and burns if the methods they described are accurately followed; and Valentine<sup>11</sup> records that a 0.1% solution rapidly cures Morax-Axenfeld infections of the eye. Apart from local necrosis and irritation of adjacent skin when used in high concentration, no toxic reaction has been reported in man after the use of propamidine; but this is probably due to its use mostly by local application. Its effects in animals are like those caused by other diamidines.

Besides the late toxic manifestations described above the intravenous injection of stilbamidine is accompanied by unpleasant reactions. These immediate reactions can be divided into mild, moderate, and severe. Mild reactions are a burning sensation over the body, flushing of the face, and slight giddiness; moderate reactions combine these symptoms with vomiting, epigastric distress, dyspnoea, feebleness of pulse, and sweating; finally, in severe reactions the patient collapses with a steep fall in blood pressure and loss of pulse at the wrist. These reactions have, happily, so far not proved dangerous to life, and can be prevented to a great extent and cured by adrenaline; Wien<sup>12</sup> showed that the fall in blood pressure can be avoided by a previous injection of calcium gluconate. Devine<sup>13</sup> has described the toxic action of stilbamidine on the liver and kidneys in rabbits; these animals showed transient hyperglycaemia and marked nitrogen retention, but death took place in hypoglycaemia. Wien, Freeman, and Scotcher<sup>14</sup> confirmed these findings, and further showed that in dogs and rabbits the serum calcium and potassium levels both fell within a few hours. Certain patients with Sudanese leishmaniasis treated with stilbamidine developed vomiting and loss of weight some months after the disease had been cured. Some of them died with signs suggesting hepatic failure. Fulton and Yorke<sup>15</sup> showed that solutions of stilbamidine undergo a change when exposed to light which greatly increases their immediate toxicity for mice, and thought that this may have been the cause of these mishaps.

The diamidine group of drugs are undoubtedly a valuable addition to chemotherapy. They may replace the antimony group and tryparsamide in the treatment of kala-azar and sleeping sickness, especially since these drugs are not any less toxic. Propamidine deserves a much wider therapeutic trial in the treatment of wound infections than it has so far received. At the same time there is a large field of investigation to complete the story of the toxicity and metabolism of these drugs.

## DIAMIDINE COMPOUNDS FOR KALA-AZAR

For many years pentavalent antimony compounds have been successfully used in the treatment of kala-azar and in India many thousands of cases have been so treated with a very high percentage of cures. Recently, as the outcome of the work of the late Warrington Yorke and his collaborators, certain aromatic diamidine compounds of a non-antimonial character have also been found effective against this disease. Among compounds of this type kind that have been successfully tried are 4:4'-diamidino-stilbene (stilbamidine), 4:4'-diamidino-diphenoxy-propane (propamidine), and 4:4'-diamidino-diphenoxy-pentane. In a recent communication<sup>1</sup> Napier and Sen Gupta give a careful and valuable analysis of the result of treatment by them of 32 cases of Indian kala-azar by the last compound and in the same number of the *Indian Medical Gazette* the latter author has discussed in an initial editorial the present position in respect to treatment by these new drugs and the pentavalent antimony compounds hitherto in general use. Of the 32 cases treated by Napier and Sen Gupta 21 are classed as "ordinary" and 11 as "resistant" cases. Resistant cases are defined as those in which an ordinary efficient course of treatment (in the present case mostly by antimonial compounds) has failed to effect a cure, or which showed a relapse after a full course of treatment. In the result 19 of the ordinary cases and 10 of the resistant cases were apparently cured, though at the time of writing none of them had been under observation long enough to exclude all possibility of relapse. In one case only was the drug entirely unsuccessful, though two full courses of injections were given. A notable feature was that intravenous administration of the drug was unattended by any serious or alarming "side effects," the immediate reactions to injections being similar to, but very much milder in degree than, those occurring after diamidino-stilbene. Further, no case resembling post-diamidino-stilbene neuropathy<sup>2</sup> was encountered. (The toxicity of the diamidines is discussed in a leading article.)

What are the advantages and disadvantages of diamidino-diphenoxy-pentane as compared with treatment by antimonial compounds and diamidino-stilbene? These are discussed by Sen Gupta in the editorial referred to. In the first place the pentavalent antimonial compounds have been found to cure about 95% of cases in India and are noted for their ease of administration and the extreme rarity of unpleasant reactions. For treatment of the great majority of ordinary cases of kala-azar these therefore still remain the drugs of choice. But for the treatment of those cases that do not respond to the pentavalent antimonials (the resistant cases), whether in India or in the Sudan, diamidino-stilbene is indicated. Diamidino-diphenoxy-pentane possesses a well-marked curative action in kala-azar, in both the Sudan and the Indian forms, but it is less efficient than diamidino-stilbene. In the Sudan it has an immediate cure rate of 75%, and for the Indian form a little higher, as against 95-98% for diamidino-stilbene. Further, as is evident from the cases now recorded by Napier and Sen Gupta, it does not eliminate the difficulty of the resistant case, though a resistant case to one drug may not coincide with a resistant case to the other. But diamidino-stilbene has the disadvantage of producing unpleasant reactions, which diamidino-diphenoxy-pentane does not exhibit, making the former unsuitable for use except in hospital or where special precautions can be adopted. Both the analysis of cases treated by diamidino-diphenoxy-pentane and the editorial on the

general question of the use of these new diamidine compounds, reflecting as they do the unique experience of the authors in this field, should be a most valuable contribution to all who have occasion to treat cases, especially resistant cases, of this disease.

## VENEREAL DISEASE IN SCOTLAND

The report on venereal diseases recently submitted by the Medical Advisory Committee (Scotland) for the most part follows generally accepted lines. After reviewing the statistics of incidence—including the naive statement that "over the past four years at least 58,000 persons in Scotland were admittedly exposed to the risk of acquiring infection"—the committee recommends that the anti-V.D. campaign should include education, prevention, treatment, contact tracing, steps to reduce defaulting, and further legislation. Education should be intensified so as to reach the general public at large and the individual in particular: instillation of a healthy fear of V.D. is all to the good, and more use should be made of the Press. The problem is a moral as well as a medical one, and the Church should play its part by teaching that chastity is the only sure method of avoiding V.D. Education of the young is a very difficult problem, and the committee—very wisely, most will think—does not recommend sex teaching to young people of the 14-15 age group but rather "health" education. Instruction in sex matters and V.D. should be given at a later age, and by selected medical practitioners. Ignorance of venereal disease, what it is and what it may lead to, is one of the great difficulties, and the responsibility for education and publicity should primarily be the duty of the Department of Health, which, however, will probably be glad to avail itself of the services of medical officers of health and voluntary bodies.

The committee favours prophylaxis, but realizes that "other weighty aspects of the problem must be considered before any final conclusions can be formed"; here it is on very delicate ground, and many think that the disadvantages outweigh the advantages. Official approval of prophylaxis may engender a false sense of security and also offend the social and moral code. Is it practicable to provide it universally? Will it be used efficiently? May it not lead to increased promiscuity? And may it not produce latent disease difficult to cure? These are some of the questions raised. On the side of medical organization stress is laid on the provision of laboratory facilities, which should be improved in both quality and quantity: here one is led to ask what proportion of serum tests for syphilis is carried out by really reliable pathologists experienced in the technique. More general blood testing for possible syphilis is needed, especially in pregnant women. Treatment centres should be improved and better distributed. The quality of the service leaves room for improvement both on the clinical side and as regards accommodation, waiting-rooms, etc. Clinics should be parts of general hospitals and not separate self-contained institutions. The patient should be treated with every consideration, and each centre should have a trained staff to deal with the sociological and epidemiological sides. The general practitioner must be included in any venereal disease scheme; his interest in the problem should be aroused; postgraduate courses and laboratory facilities should be available; and medical students should be taught both the clinical and the epidemiological aspects of venereal disease as part of the medical curriculum.

Tracing of contacts and the follow-up of defaulters are two very important sides of the campaign and should be

<sup>1</sup> *Ind. med. Gaz.*, 1943, 78, 177.

<sup>2</sup> Napier, L. E., and Sen Gupta, P. C., *ibid.*, 1942, 77, 71.

undertaken by the Department of Health itself. Merchant seamen are stated to have brought much venereal disease into Scotland, and present perhaps the most difficult problem of all. Amenities should be provided in the ports, and treatment should be readily available. In this connexion a method—not mentioned by the committee—of dealing with early syphilis seems worthy of consideration: i.e., the twenty-day treatment with arsenoxide and bismuth; the whole course is concentrated into a single period of three weeks, and the difficulty of getting injections at various ports is thus eliminated.

The committee thinks that Regulation 33B serves a useful purpose. Its recommendation of "notification," even though anonymous, is likely to meet much opposition, except so far as ophthalmia neonatorum and congenital syphilis are concerned. Will a general practitioner notify his cases, and will he notify the M.O.H. when such patients default? In those countries where notification is compulsory the evidence that it works is inconclusive. It is not the known sufferers who apply for treatment which are the danger, but the infected persons who remain untreated. Nevertheless, the committee's recommendation of compulsory notification was made after weighty consideration. There is no logical argument against notification if venereal diseases are to be regarded as communicable infections endangering the community as much as, if not more than, typhoid fever or measles. The real test is whether notification will or will not promote control of these diseases.

### TYROSINE POISONING

Tyrosine is a key amino-acid, essential for the biosynthesis of adrenaline, melanin, thyroxine, and the hormone of the posterior pituitary. There is some evidence, however, that in addition to its useful functions it may be indirectly connected with the pathogenesis of certain diseases. As a precursor of tyramine, which has a pressor action, it has been related to the causation of hypertension, while as the precursor of melanin it has been suspected as a factor responsible for the occurrence of primary cancer of the liver among coloured peoples. Disturbances of tyrosine metabolism in certain diseases have been noted. Thus Umber<sup>1</sup> and Weiss<sup>2</sup> commented on the urinary excretion of tyrosine in diabetes, hepatic diseases, and in the frequently coexisting pancreatitis. Bickel<sup>3</sup> also noted that tyrosine prevents glycogen storage in the liver, and pointed out its possible importance in the dietary management of diabetes. Litzka<sup>4</sup> observed that tyrosine reduces the blood sugar in patients with exophthalmic goitre, and Abelin,<sup>5</sup> on the basis of animal data, recommended its administration to patients with hyperthyroidism. Abelin claimed that tyrosine is rapidly metabolized and can be given in large quantities without ill effects. This view was supported by Abderhalden,<sup>6</sup> who took 50 to 150 g. of the substance without any apparent untoward effects. But later work by Hueper and Martin<sup>7, 8</sup> suggests the contrary. Rats given tyrosine developed purulent keratitis and redness and oedema of the extremities within a week or two and died shortly after. Post mortem there were degenerative necrotic and fibrotic changes in the pancreas, leading to destruction of both parenchyma and islet tissue. Degener-

ative and necrotic changes were observed in the kidneys, and in the arterioles of the brain, heart, lungs, and kidneys there were swelling and hyalinization of the media and proliferation of the intima, associated with focal haemorrhage, necrosis, and glia-cell formation in the brain. There was also evidence of hypertension. The association of diseases of the biliary system, pancreatitis, and diabetes with tyrosinaemia in conjunction with the observations of Hueper and Martin<sup>8</sup> suggests a possible connexion between these diseases and disturbed tyrosine metabolism. The degenerative arterial changes and hypertension may have been due to the formation of the vasopressor tyramine from tyrosine, or the conversion of the latter into abnormally large amounts of adrenaline or a vasopressor hormone of the thyroid or posterior pituitary. The observations of Hueper and Martin should serve as a warning against the use of excessive amounts of tyrosine for therapeutic purposes, as in the proposed treatment of thyrotoxicosis. Tyrosine is a normal constituent of protein and an essential factor in nutrition. Toxic effects will not occur from the ingestion of the quantities present in a normal diet.

### CORNEAL DYSTROPHY

Corneal opacities of non-inflammatory origin were clearly recognized by Groenouw in 1890. The subsequent literature brought, in the first place, confusion owing to the fact that different observers gave different names to opacities of this kind, and, secondly, some clarification from the recognition that the affection had hereditary features, being sometimes dominant in transmission and at times recessive. A much-needed clarification of the position came with an excellent monograph by Bücklers<sup>1</sup> in 1938. Summarizing the copious literature on the subject and reporting on 129 patients, he was able to correlate clinical and genetic factors and establish three forms of corneal dystrophy: (1) Recessive corneal dystrophy, appearing early in life and running a severe course, the corneal lesion being "macular" or "nodular"—i.e., fairly gross opacities tending to cover the whole of the cornea. (2) Dominant reticular corneal dystrophy, running a less severe course, but still heavily affecting vision, the lesion consisting essentially of interlacing lines and nodules and tending to be confined to the centre of the cornea. (3) Dominant granular type, the mildest of the three varieties, in which there are irregular discrete granules tending to be confined to the centre of the cornea and generally not making their appearance till middle age. This classification was taken over by Franceschetti and Streiff in 1940 in their comprehensive article<sup>2</sup> on corneal dystrophies, and is also used by J. R. Mutch in a more recent publication<sup>3</sup> in reporting an extensive family with dominant granular corneal dystrophy. The basis of these dystrophies is unknown, and Mutch was able to establish the negative fact that there is no correlation between corneal dystrophy and blood grouping.

The attacks of pain and injection to which patients with the recessive nodular type and the dominant granular type are prone may make the diagnosis of corneal dystrophy as distinct from an inflammatory corneal reaction a matter of some difficulty. The clear recognition of these pitfalls is essential if much futile and perhaps harmful treatment is to be avoided. So far the most helpful therapeutic approach, tentatively advocated by Franceschetti and Streiff, is corneal grafting for the more severe forms.

# The truth about Vitamins

## GOVERNMENT DECISION WELCOMED

Recent action by the Ministry of Food should go a long way towards putting an end to spurious, or even doubtful, vitamin claims. A recent White Paper contained this sentence:—

*"After consultation with the Medical Research Council the Government have decided that a similar quantitative disclosure of the vitamin or mineral content shall also be required in the case of foods in which the presence of these constituents is claimed."*

Foods claiming to contain vitamins are to be put on the same footing as products recommended as medicines in which the presence of vitamins is claimed, where quantitative disclosure is already necessary.

No alteration of policy or practice will be entailed in the case of Bemax, the vitamin content of which has been disclosed on every package for many years.

### Distribution of Bemax

The appropriate Ministries have asked that Bemax should be reserved for those taking it on medical advice.

Priority is accorded to hospitals, Public Health Authorities, clinics, doctors and the Red Cross.

Direct orders from members of the medical profession will, as heretofore, be given priority. Supplies cannot, however, be forwarded direct to patients.

There is no formal rationing scheme for the public but chemists are co-operating with us to secure equitable distribution.

1 oz. of BEMAX supplies, at time of manufacture, approximately:

Vitamin A	280 I.U.	Manganese	4.0 mg.
Vitamin B <sub>1</sub>	240-420 I.U.	Iron	2.7 mg.
Vitamin B <sub>2</sub> (riboflavin)	0.3 mg.	Copper	0.45 mg.
P.P. factor	1.7 mg.	Protein	33%
Vitamin B <sub>6</sub>	0.45 mg.	Avail. Carbohydrate	39%
Vitamin E	8 mg.	Fibre	2%
		Calorific Value	104

Vitamins Ltd., 23, Upper Mall, London, W.6.

### MORYL

TRADE MARK

CARBACHOL

BRAND

#### Parasympathetic Stimulant

A powerful stimulant of the parasympathetic nervous system, chemically related to acetylcholine, but more active and more stable. Indicated more especially in post-operative intestinal stasis and urinary retention. "Moryl" is also useful in eclampsia and pre-eclamptic conditions, hypertension, paroxysmal tachycardia, anxiety neurosis, ozaena and glaucoma.

### TETRONOX

TRADE MARK

TABLETS

BRAND

#### Hypnotic—Sedative

Enhanced power of barbitone through careful combination with other drugs—reduced toxicity; no cumulative action or injurious effects on circulation, respiration or gastro-intestinal tract. "Tetronox" has a wide field of indications in psychiatry and is furthermore of value in menstrual discomforts, post-operative and post-partum sedation, occupational insomnia, premature waking, etc.

# MERSALYL B.D.H.

*The Standard Mercurial Diuretic*

Mersalyl is accepted as the standard mercurial diuretic; it is indicated principally for the treatment of ascites and œdema of cardiac and cardio-renal origin and ascites due to hepatic cirrhosis.

Mersalyl B.D.H. is normally administered by injection, for which purpose it is available in ampoules (Inj. Mersalyl. B.P.). For supplementary treatment in prolonging the diuresis induced by an injection, Mersalyl B.D.H. is available in tablets (containing mersalyl 0.08 grm. and theophylline 0.04 grm.) for oral administration and in suppositories (containing mersalyl 0.4 grm. and theophylline 0.2 grm.) for rectal use.

*Details of dosage and other relevant information will be gladly supplied on request.*

## THYROID THERAPY *with*

TRADE **ELITYRAN** MARK

Brand of THYROID EXTRACT

'Elityran' possesses the full therapeutic effect of the thyroid gland, and, in spite of its high iodine content, there is a lessened liability to the usual by-effects of thyroid medication. Prolonged thyroid treatment in small doses is indicated in hypothyroidism occurring in youth and, with the addition of a suitably chosen calorie-poor diet, the dosage can be kept at a minimum in cases of obesity.

Issued in tablets in 30's, 100's, 250's, and 1,000's

## VITAMIN THERAPY *with*

TRADE **BETAXAN** MARK

Brand of ANEURINE HYDROCHLORIDE

There is some evidence to suggest that Vitamin B<sub>1</sub> (in 100 mg. doses) may be used with advantage for the treatment and relief of symptoms arising from "dry socket." Similar concentrations are suggested for the rapid introduction of relatively large quantities of Vitamin B<sub>1</sub>, especially in post-anaesthetic depletion of reserves and for addition to glucose-saline transfusion.

New packings—Ampoules of 100 mg. in boxes of 3 and 15  
Other packings—Ampoules 5 mg., 25 mg., Solution 250 mg.  
in 10 c.c. Tablets—1 mg., 3 mg.

## POSTPONEMENT OF ANNUAL REPRESENTATIVE MEETING AND PANEL CONFERENCE

### MINISTER OF HEALTH'S LETTER

As announced in the *Supplement* this week (p. 121), the Annual Representative Meeting of the B.M.A., which was to have been held in July, and the Panel Conference fixed for June, have, at the request of the Minister of Health, been postponed. The following is the Minister's letter:

Ministry of Health,  
Whitehall, S.W. 1

May 22, 1944

SIR.—I am directed by the Minister of Health to say that your letter of May 17 addressed to the Secretary of the Ministry of War Transport, regarding the holding of conferences at the present time, has been referred to him. Mr. Willink wishes me to say that, as stated in the recent Press notice, it is desired in view of the difficulties of transport, to avoid the calling of conferences involving travel over long distances, and he greatly regrets, therefore, that the answer to your question must be that the proposed Conference of the British Medical Association in July should, in his opinion, be postponed. He fears that he must also express the same opinion about the Panel Conference which, he understands, has been arranged for June 28.

The Minister naturally regrets any step however unavoidable, which may delay discussions with your Association regarding the proposals in the White Paper for a National Health Service, but he hopes that it will be possible to arrange for the holding of the Conferences later in the year, and he will communicate with you again as soon as it is possible to inform you of the removal of the present restrictions.

I am, Sir, your obedient servant.

(Signed) ARTHUR N. RUCKER.

Dr. Charles Hill,

Secretary,

British Medical Association.

### PROGRESS IN MENTAL HYGIENE

A special meeting of the National Council for Mental Hygiene was held recently under the chairmanship of Lord Alness. The Duchess of Kent, the president of the Council, attended and said a few words on the important part which it had to play in relation to the mental health of the people, especially in view of the accumulated strains of war.

Dr. Helen Boyle, chairman of the Council, recalled the little-known history of its foundation. It could be traced to the publication in America of a book entitled *A Mind that Found Itself*, by C. W. Beers, in which the need for a central organization to give practical direction to ideas on the subject of mental hygiene was stressed. The result was the formation in America of the Committee for Mental Hygiene, and following upon her own visit to the States just after the last war Dr. Boyle succeeded in getting people in Great Britain interested in the same idea, particularly Sir Maurice Craig, a pioneer in the treatment of early mental cases. Dr. Boyle referred to the advances in mental care signified by the Mental Treatment Act, with the admission of voluntary patients to mental hospitals and the provision of clinics. Treatment itself had been greatly improved, but one of the most important changes was the change in public opinion concerning mental cases. In the propaganda necessary to bring about this change the Council had had a considerable share. She hoped that when the war was over something of the comradeship which had been forthcoming in wartime would survive. A very desirable innovation would be some form of club with accommodation for parents and children, because the present provision of recreative facilities tended to separate members of families. In particular the housewife should have some provision which she could enjoy with the rest of her family, for after her experience of real social contacts during the war she was likely to feel lonely and bored, to the detriment of her mental health.

The proceedings ended with the showing of a psychological film entitled *Fear and Peter Brown*, a cleverly drawn picture of a child frightened of the dark, with its fears unallayed by its parents, and growing up into a nervous individual afraid to face life.

## Nova et Vetera

### EARLY MEDICAL WORKS IN EDINBURGH UNIVERSITY LIBRARY

To illustrate a current series of lectures on "The Historical Background to Modern Medicine" there has been placed on view a collection of early printed medical books in the Upper Library Hall of Edinburgh University. Founded in 1580 as a "Town's Library" three years before the foundation of the University, or "Town's College," the University Library remained the only public library in Edinburgh until the establishment of the Advocates' Library a hundred years later. Naturally it contains many treasures, including a number of works of medical interest from which the present selection has been made.

The following are a few of the leading items. Greek classics are represented by the first printed editions of the works of Dioscorides (1499) and of Hippocrates (1536), both from the press of Aldus of Venice, also by the Basel edition of part of the writings of Galen (1536). Arab writers are exemplified by the *Opus medicinarum practicae* of Rhazes, printed at The Hague in 1533, and by two fine editions of Avicenna's *Canon Medicinarum*, one from Venice, dated 1608 (the other, a modern version in Urdu, which appeared at Lucknow in 1887, when this 10th century work was still used by native practitioners of India. There is also on view a beautiful copy of one of the first illustrated textbooks of surgery, Albucasis's *De Chirurgia*, in Arabic and Latin (Oxford 1778). In manuscript form, this is said to have been the leading work on surgery in the Middle Ages. The adjoining cabinet contains four early editions of the popular poem, the *Regimen Sanitatis Salernitanum*, the earliest dated 1486, and the *Chirurgia magna* of Paracelsus (1573). Close by is that early handbook for midwives, now very rare, Eucharius Ruesslin's *De partu hominis* (Frankfurt, 1532). Similar works are Ruell's *De conceptu et generatione hominis* (1587) and the English translation, *The Expert Midwife* (1647). A well-known book of the same nature, and also a great rarity, is Raynalde's *Birth of Mankind* (1564), though the copy on view is not the first edition (1540). An interesting item in the 17th century section is the *Cerebri Anatome* of Thomas Willis, illustrated by his friend (Sir) Christopher Wren. Of the same period is a volume of Zodius's *Medico-gallicus*, the Latin version of the first medical periodical, *Nouvelles Descouvertes*, founded at Paris in 1679 by Nicolas de Blegny.

The most important and valuable items in the exhibition, however, are the two greatest books in all medical literature, Vesalius's *De Corporis Humani Fabrica* and Harvey's *De Motu Cordis*. The beautifully bound copy of the former is the first edition, from the press of Oporonius of Basel, 1543. Beside it lies the fine two-volume edition, printed at Leyden in 1728, by Boerhaave and Albinus. The first edition of Harvey's account of the circulation of the blood is now an extremely rare little book, dated from Frankfurt, 1628. Visitors to the exhibition have the opportunity of seeing two perfect copies, one of which belonged to Alexander Monro, the third of the dynasty of professors of anatomy of that name. The first Alexander Monro, when appointed to the chair in 1720, kept a list of his students, which is now shown, as also is a printed copy of the first thesis to be presented for the degree of M.D. Edinburgh. It is entitled "De Dolore," by John Monteith, and the date is 1726. Another manuscript relating to the Edinburgh Medical School is a letter of advice, dated Feb. 10, 1704, from Dr. Archibald Pitcairne, one of its founders, to his patient the Earl of Wintoun. The adjoining copy of Pitcairne's *Dissertationes Medicae* bears the author's seals and signature.

Later works on view are the second edition (1800) of Edward Jenner's *Inquiry into the causes and effects of variolae vaccinae*, the first British edition of Beaumont's *Experiments and Observations on the gastric juice* (1838), Morton's *Remarks on the mode of administering ether* (1847), and J. Y. Simpson's *Account of a new anaesthetic agent* (chloroform), 1847. Another landmark of medical literature is Lister's *Introductory Lecture*, delivered in 1869 when he succeeded James Syme in the chair of clinical surgery at Edinburgh, and with it may be seen a manuscript set of notes of Lister's lectures, in the writing of one of his most distinguished students and successors, Prof. Caird.

A feature of the exhibition, and the most spectacular item, is a fine collection of illustrated Herbals, including a magnificent copy of *De Historia Stirpium*, by Leonard Fuchs (of fuchsia fame), dated 1542, with lovely coloured woodcuts, and a catalogue of the Physic Garden of Edinburgh (1683), by the first professor of botany, James Sutherland.

The exhibition, which has been arranged through the kindness of Dr. Sharp and the Library Committee of the University, will remain open daily from 10 to 4 (except Saturday and Sunday) until the end of May.

D. G.

## Correspondence

### Medical Education: Principles and Method

SIR,—Most readers will agree with your view that the report on medical education of the Planning Committee of the Royal College of Physicians is a welcome advance upon its predecessors on social and on psychological medicine in that it proposes a coherent scheme of education, and not the extensive additions to the present overgrown and obsolete structure that they advocated.

Yet it may be submitted that, for a report intended as a guide to action for university and other bodies sharing responsibility for medical education, it lacks the clear definition and exposition of its operative terms essential to this end. Thus, in one of its key paragraphs—namely, para. 62—the word “method” occurs on almost every line, but it is used in a different sense in each case: referring now to techniques, now to observation, and now to the inductive process. In the last sense it is substituted by the word “principle” at one stage of the argument, and we are finally told that “method” and “principle” are two distinct objectives. The final impression left by this important paragraph is one of incoherence, and the reader feels that these significant words have been used rather as detonators, creating an impression on the reader, but conveying no information because they embody no clearly thought out notions in the minds of the authors.

Now, the distinction between the theoretical and vocational elements in a medical training is one not universally appreciated, and it was therefore the more essential that the report should have been clear and explicit about them, that it should define its terms, use them consistently, and exemplify them adequately. All these the report signally fails to do, and thus may be said not to have risen to the height of what should be a vital occasion in the history of medical education. No one seeking to learn what are the principles and method in which the medical student should be grounded will find the answer in the report.

As a clinical teacher I have been impressed by the ignorance betrayed by the medical student coming to hospital fresh from his pre-clinical studies of what may be called the general principles of scientific thought; those we speak of as natural laws, and the processes by which we can know anything—that is, the structure of experience. I have yet to meet such a student who has a clear idea of what is meant by a natural law or how it is defined, who realizes that all science comes from the meeting of the observational and conceptual orders of experience, appreciates the distinctions between the two, what notions belong to the one and what to the other, or who has any idea of the limitations of the observational order. Yet most of them are bursting with facts about the most recondite chemistry of the vitamins and the most recent techniques of electrophysiology, which have burdened their memories to little purpose. I suggest that this is because the teachers of the pre-clinical subjects are themselves bogged in their own techniques, and entertain nothing more general in the way of ideas than unrelated snippets of theory belonging to these techniques. They do not teach the general principles that underlie and should unite all scientific disciplines. Yet surely we have the right to expect that, after three years at least devoted to scientific studies, the student should know the rudiments of the principles involved in scientific thought and method. Nothing is clearer than that he does not, and by the time he reaches the clinical teacher it is already too late to change his entire way of thought. If the new medical graduate emerges finally from his tutelage merely the incomplete master of a number of unrelated techniques the clinical teacher is neither wholly nor primarily to blame. Reform must begin at the beginning of the medical course.

Finally, it may be permitted to doubt whether intelligence tests will solve the difficult problem of selecting students for the medical course. These assess only an arbitrarily chosen fraction of the human mind, and are carried out by wholly unstandardized performers. It is an odd commentary on current opinion on this subject that we should be so ready

to accept, as adequate tests, procedures carried out by uncalibrated human instruments. When shall we test our intelligence testers? Students of Whitehead's *Modes of Thought* and *Adventures of Ideas* will appreciate the inadequacy of current ideas among scientists as to the nature and mode of action of intelligence, and the sources from which the structure of experience is built. Trotter, also, in his lecture, “Has the Intellect a Function?” has indicated that more realistic ideas on the subject are a necessary preliminary to any satisfactory calibration of the intellect.—I am, etc.,

London, W.1.

F. M. R. WALSHIE.

### Medical Education: Need for Staff College

SIR,—One's first reaction to the Report of the Planning Committee of the Royal College of Physicians is a feeling that the College might have done something about it sooner. For generations the influence of the two Colleges over the medical course has been paramount. Nearly all the students in England and Wales have taken their examinations as their first qualification, and these examinations have largely, if not entirely, determined the scope and type of the teaching given in the schools. The officials and examiners of the Colleges have all themselves been teachers. The College of Physicians, therefore, cannot evade its share of blame for perpetuating a system which it now condemns in such vigorous terms. But not a moan of contrition, not a sob of remorse can be heard from Pall Mall East.

The committee has taken as its model Karl Pearson's dictum that “the true aim of the teacher should be to impart an appreciation of method”; surely the most narrow-minded definition ever proposed. In consequence, although it set out with the avowed object of improving the course as an education it has merely succeeded in suggesting improvements in technical instruction. One searches in vain for a vision of the problem from the broad philosophic point of view, of the kind which has been outlined by Sir Thomas Lewis and Dr. F. M. R. Walshe.

Many of the recommendations were well within the power of the schools to carry out on their own initiative. Pre-clinical teachers, says the report, should make use of clinical material. But clinical material has been theirs for the asking; they have not wanted it. Pre-clinical teachers, says the report, should be attached to clinical departments. But for years clinicians have been begging pre-clinical teachers to go into the wards; and still they don't go for the simple reason that they don't want to go. These and similar recommendations will never overcome the tremendous strength of tradition and of the centrifugal force of departmentalism unless their advantages are conclusively demonstrated. They will merely be adopted in a perfunctory manner and quietly allowed to sink into oblivion.

However attractive the recommendations may look on paper there is no guarantee that they would stand the test of experience. The curriculum has grown up haphazard on expediency and opportunism, lacking natural cohesive elements and having little basis in the fundamental principles of education, and its reform must be undertaken not by adjustments of the existing structure but by building a new structure on more solid foundations. This task can only be accomplished by the experimental method. We hear enough about the need for research into the causes of disease, but barely a word about the need for research into the teaching of disease.

The report totally ignores the crux of the problem—the training of teachers. While rightly anxious to protect the public from inefficient doctors it suggests no means to protect students from inefficient instructors. The committee is under the illusion that when satisfactory conditions have been provided skilled teachers will drop from the sky. It is an astonishing fact that the training of teachers is most intensive at the lowest level of education and non-existent at the top. Elementary school teachers spend two years in acquiring proficiency learning the principles and psychology of education, studying the works of Spencer and others, and the theories underlying the various methods in vogue—such as the Froebel and “project” method—and receiving practical instruction in teaching. Yet although medicine is at least as difficult to undergraduates as the alphabet is to infants no attention has

ever been paid to ensuring the competence of its teachers as teachers. No system of teaching medicine based on fundamental principles has ever been formulated and tested.

The solution of the problem lies in the creation of a staff college. A medical school attached to a university should be set aside for the purpose. It should have a normal complement of undergraduate students, and its staff should include an experienced lay educationist. Its functions would be to build up a system of medical education and to train clinical teachers. The staff would study the curriculum as a whole and the modification and co-ordination of its component parts. Disease would be studied from its educational aspect by clinical and pre-clinical teachers, including teachers of the basic sciences. Plans decided upon would be tried out on the students and modified according to experience. The staff would also frame the most suitable manuals of instruction, explore the possibilities of special methods such as the use of working models and the cinematograph, and they should establish contact with the Dominions and the United States for the exchange of ideas and teachers.

Courses of instruction would be provided for men aspiring to staff appointments at other schools. These would learn the principles and psychology of general education from the lay educationist, the history of medicine, and the theory underlying the system adopted at the staff college, how it had been arrived at, and what modifications were under consideration. They would learn the art of teaching medicine by listening to the staff and by giving lectures themselves under supervision. They would also learn the difficult art of examining candidates. There would be no need to give the staff college powers to enforce its system on other schools. It would be open to suggestions from outside, but by virtue of the attention it had given to the problem it could not fail to exert a considerable influence on the schools, and it would play a conspicuous part in improving existing schools and creating new ones throughout the Empire.

Any plan to reform the curriculum from the standpoint of medicine alone is doomed to failure. The problem must be approached from the standpoints of medicine and of education combined.—I am, etc.,

Cambridge.

FF ROBERTS.

### Character and Personality in the Medical Student

SIR,—“In future Mrs. Smith's son of Back Alley, Anywhere, may be a doctor”; thus one of the leading daily papers reports the Planning Committee of the College of Physicians. In these days of the social conscience extraordinary indeed are the lengths to which the apotheosis of the so-called under-dog is carried; and, by inference, also the belittlement not merely of wealth and position but of eminence of almost every kind, including wisdom, learning, and refinement. The committee, of which Lord Moran is chairman, point quite rightly to the importance of personality and character in the medical student, traits which they discover to be lacking at the present time. They conclude that the reason for this is that the field of selection is too narrow, and recommend that it should be widened by making all university education free. It is true that a widening of the field will result in all probability in an increased number of candidates for the medical profession, but it by no means follows that it will improve the quality in the direction of character and personality. Indeed it is arguable that the indiscriminate widening of the field with no attempt to sort the wheat from the tares, which has been the trend of the past thirty years, is itself responsible for the deterioration. If that is so, then yet another learned body has added its quota to the general bemusement.

The trouble here, as with other problems of sociology, arises from a failure to grasp at fundamentals. Instead of digging for the root, reformers trim the stem with this or that placebo, and the effect as often as not is a dozen more problems and aggravations in place of one. In this case, as in many others, the fundamental is to be sought in the influence of heredity and of early home life. Millions of pounds are wasted annually in an effort to inculcate traits of character which are hereditarily non-existent, and to germinate ethics of civilization which are promptly and effectively annulled in any home where ignorance, stupidity, idleness, dirt, and vice are the pattern.

Taking the broadest view without prejudice and allowing for the accidents of good and bad fortune, of good and ill health, and, above all, for the waywardness of Nature, it is fair to assume that those who have attained a certain high standard of living have done so by virtue of either their own character or that of their forebears; and, if the laws of heredity have any validity at all, it may be expected that a not inconsiderable proportion of them will pass on those traits to their successors. On the other hand, though it would be wrong to exclude all resources, the most fruitful field of higher civilization is little likely to be found in the worst types of home. Yet that is the conclusion to be formed from the outpourings of some of our social reformers, and the Government, in obedience to the loudest clamour, gives almost direct encouragement to the least worthy to reproduce themselves in the greatest numbers and a corresponding discouragement to their betters. Where can such a policy end but in the deterioration of the race? The laws of heredity and the breeding of the best stock are recognized and practised by man. They are ignored and Nature flouted by man himself solely in relation to himself.

Wealth and position are dangerous side-issues. They are the concomitants as they are often the downfall of eminence. They are not, however, evil in themselves; indeed, they often foster the very best and highest of human characteristics; they are bad only when they become stagnant, unproductive, and surfeited with plenty. Eminent men not infrequently marry empty-headed women, and succeeding generations deteriorate. The Government spends more and more on so-called social reforms, and enters more and more into the control of human lives. As State control, over-industrialization, and over-population increase, so individuality, personality, and character are being ironed out and gradually we become a race of automatons. How can it be wondered at if the medical schools are crowded with men with brains but no character, with precepts but no principles? Decent living, refinement of speech and of conduct, love of poetry or the arts, of good conversation, of wisdom, of learning—all these have been at a discount and have even been scoffed at in the physical and mental squalor of the years between the wars. And now lest any doctor should retain a trace of spirit or of individuality the medical profession is to be centrally controlled and directed; and, harnessed to the Civil Service, is to become the chattel of politics. Where among our leaders are the honest thinkers, outspoken and fearless of unpopularity, who will bear witness to truth, which is as old as the world and as solid and as plain to see.—I am, etc.,

Derby

E. D. BROSTER.

### Eugenic Value of Goitre Elimination

SIR,—The recent memorandum of the Medical Research Council on “Endemic Goitre in England” demonstrates clearly the very marked prevalence of goitre in our community at large. For many years I have been endeavouring to direct attention to this obvious indication of a great and increasing iodine deficiency in our people, and have stressed its deleterious effects upon the general health.

Our future depends upon the health of the nation's mothers and their children, and one must bear in mind that the great majority of our expectant mothers are suffering from iodine deficiency, and in addition to the ill effects this condition may have upon them it is apparent that their offspring are apt to be handicapped even from conception in both their physical and mental development and to be born into a new environment with suboptimal preparation to face the exigencies thereof; in fact, they are not *eugenic* (well-born). I have been urging that no expectant mother should continue to suffer from iodine deficiency, and the same, of course, applies to the community in general.—I am, etc.,

Penarth.

W. MITCHELL STEVENS.

### Water and Population

SIR,—With reference to Prof. D. B. Blacklock's article (Dec. 25, 1943, p. 805) on the population of India, it recalls a discussion I had in Egypt with the Engineer of Water Supply. He gave me the population of Egypt, and said, “If I can provide more water there will be an increase, I think, of about two million people.” I naturally asked, “What happens then?” The reply was, “I know of no solution.”

The same thing is now occurring in India. Sooner or later we must face an insoluble problem. All the hygienic measures may and probably will defer the impasse but cannot prevent overcrowding. The international problem which will arise can be serious enough in all conscience.

So far the only great country with no immediate trouble and with very great resources is Russia. Even the United States, owning, according to Siegfried, half the wealth of the world, will feel it ultimately. It is one of the world's problems which must be faced.

The vast areas in Australia are very sparsely populated because of the lack of water and no means so far of increasing it. They can grow merino sheep, but cannot carry a large population, though the sheep can supply other countries with wool and a certain amount of food. On the coastal fringe where there is water the population can and does increase, but, like the east end of Java and the Sunda Islands, where the climate is similar to Northern Australia, the same trouble occurs, except near the volcanoes, which provide perennial water. Volcanoes in the centre of Australia would make all the difference, but these do not exist. The statesmen of the future will have much to think about.—I am, etc.,

Melbourne.

JAMES W. BARRETT.

### Immersion Foot and Cold Therapy

SIR,—In his letter (*Journal*, Feb. 26) Mr. Norman Lake criticizes certain points in the article written by Major Corbett and myself (*Journal*, Feb. 12). He thinks we imply that frost-bite and trench foot are synonymous terms, but we state clearly in our paper that trench foot is probably the same as immersion foot so long as freezing-point is not reached; at some point below this frost-bite could be superadded. We clearly drew the distinction between frost-bite on the one hand and the probably identical conditions of immersion foot and trench foot on the other hand. We were unaware that he had drawn this distinction in 1915. But evidently our article (written in December, 1942) did no harm in stressing the point, since in 1941 two such authorities as Raymond Greene and Hamilton Bailey (*Surgery of Modern Warfare*) stated that frost-bite and trench foot were probably identical. It is only fair to add that in later publications they stress the distinction. One purpose was to indicate clearly, apart from all theories, what this difference is; we stated that within the area subject to frost-bite all tissues are dead and look dead, and that in the area subject to immersion trauma there is a gradation of injury—nerve tissue suffering most, but the part as a whole is alive and looks alive.

I was impressed by the experiments of Mr. Lake in which tissue cultures were kept alive at the critical temperature of  $-5^{\circ}\text{C}.$ ; they demand no oxygen because their metabolism has been arrested. These experiments give a firmer basis for the view expressed in our article: "Warmth raises the metabolism to a point beyond the capacity of the feeble circulation to supply it. Thus the tissues are brought to a state of metabolic bankruptcy." We claim no special originality for this. Capt. Bigelow and Lanyon in the *B.M.J.* of the same date also express this opinion.

We must agree with Mr. Lake that a cold limb requires a minimal blood supply and that great dangers are involved in bringing back a normal circulation. But nevertheless we have got to bring back the blood supply to normal because we are dealing with a man's foot and not merely a tissue culture, and the circulation must be brought back sooner or later. Certainly local warmth must not be used to increase circulation, because it raises the local metabolic demands of the tissues beyond the capacity of the circulation. Certainly we must not bring back the circulation too fast, because we would only create a barrier of oedema between the tissues and their oxygen supply. Mr. Lake suggests that local vasoconstriction should be used on the affected part, but the trend of modern therapy (and not merely our view) is to produce gentle local arteriolar dilatation reflexly by allowing distant parts to become warm; this is combined with dry cold locally to reduce the metabolic needs to the capacity of the subnormal circulation. This idea is well expressed by Ungley and Blackwood (*Lancet*, Oct. 17, 1942).

All the arguments in this letter are available in our original article, as I think Mr. Lake would agree if he reads it again. He has based his criticism chiefly upon points which are a side-issue to our main thesis—this is the conception that, in immersion foot, there is a wide gradation of trauma within the injured part; we have suggested a reason for this gradation.

The delays in the publication of the original paper and of this letter are inevitable under conditions of active service.—I am, etc.,

B. W. GOLDSTONE.

### Sulphaguanidine in Flexner Dysentery

SIR,—I am grateful to those who have written regarding my article on the above subject. It is apparent that we have not reached the stage when dosage of sulphaguanidine can be precisely stated. However, as the blood levels in my series of cases showed, there is a considerable absorption of the drug. This seems to constitute substantial grounds for exercising restraint in the administration of very large doses to patients who may well be dehydrated.

The extremely high incidence of sensitization rashes in my cases also seems to provide sufficient reason for due care regarding dosage. Criticism has been directed against this chiefly on the ground that such a high incidence has not been the experience of other workers. I can only speak from my own experience. I feel, however, that some of the rashes might have been missed but for the vigilance of the nursing staff. That there were reasons, other than high dosage, to account for the unusual finding is surely too problematical for serious discussion. The importance to be attached to the occurrence of the rashes is a matter of opinion. In view of the severe effects after administration of a test dose of sulphaguanidine in patients thus sensitized, I cannot regard their occurrence with the same complacency as Brig. Bulmer. In any case, assuming that massive dosage is responsible for such toxic manifestations, their imposition on patients is not justified if an adequate lower dosage of this expensive drug can be reached.—I am, etc.,

Glasgow.

H. G. SMITH.

### Kala-azar in Malta

SIR,—Having served as a specialist sanitary officer in Malta during the last war (1915-18), I would like to support the suggestion made by Dr. R. J. Lytle (May 13, p. 670) that kala-azar was probably of more common occurrence in British adults in Malta than was generally realized.

I remember a case not previously referred to in this correspondence: that of Sister B., a member of the staff at St. George's Hospital, Malta, who contracted the infection there. The onset of her illness was insidious—gradually increasing lassitude and weakness, with loss of weight and anaemia. Apart from the increasing severity of the symptoms the only indication of an infection were a suggestive white cell change in the blood and slight enlargement of the spleen. When all other examinations had proved unavailing, splenic puncture was performed and the presence of Leishman-Donovan bodies demonstrated. Although the patient had by that time become very weak and dangerously ill, intravenous injection of antimony led to a complete recovery.—I am, etc.,

JOHN M. GIBSON,

Medical Officer of Health, Huddersfield.

### Marriage and Parenthood

SIR,—The prejudice against definite preparation for marriage which is brought out by Dr. Wrathall Rowe (May 6, p. 636) is felt acutely by all who strive to work on the lines suggested by Dr. Edward Griffith (April 15, p. 540). Such bodies as the Marriage Guidance Council, of which he is a member along with not only other medical men and women but also with progressive clergy and social workers, find their effort to spread information and advice blocked by views that are to our minds, irrational and merely emotional.

I write to suggest that the family doctor could help in dispelling ignorance much more effectively than Dr. Rowe in a fit of depression, believes. Let the value of honest simple teaching about sex be persistently urged upon parents, beginning when the first child first asks questions, and surely they will

demand, not avoid, adequate preparation for marriage when the time comes. Though ideally the family doctor should undertake the premarital examination, the fact remains that young people often find it easier to talk to a stranger. They are shy with the one who knows all about them as they often are with their parents on the deeply emotional matters connected with sex.

I must add that in my experience the outlook of the younger generation is already changing. That all girls should have good talk with a doctor before marrying is an idea frequently and warmly expressed by modern-minded girls. Some come to one for the purpose, or by women who deeply regret having married in ignorance. There is, I am convinced, a growing perception, which we ought to foster, that knowledge does not ruin romance in marriage any more than does the study of technique spoil the artist's joy in self-expression. But we do need to advise with delicacy and sympathy, and with a perception of the values beyond those expressed through the physical and psychological relationships.

The great thing at the moment, I repeat, is to back up the pioneers in insisting upon the value of adequate preparation for life's greatest adventure—that of matrimony—I am, etc.

Hove.

LILIAN M. BLACKETT JEFFRIES

### Anaesthesia in School Dental Clinics

SIR,—We have read with interest the article by Dr. K. B. Pinson on this subject (April 29, p. 588). While agreeing as will, we are sure, all school dental officers of experience, that the figure of 65% of acceptances is unduly low and would be raised, we would suggest that the use of an anaesthetic agent which so often causes nausea and vomiting is likely to delay this improvement, whatever may be the other advantages. Further, the complication of vomiting may cause considerable trouble and delay in the working of the clinic, as well as distress to parent and child.

In our clinic we have for long used nitrous oxide and administered with a Trewby nasal inhaler and commencing with pure gas; except in occasional mouth-breathers we have had very little trouble. Induction is swift, anaesthesia is seldom taken deep, and at the end of the operation the children open their eyes, walk from the chair and rinse in the recovery room. Sickness is so rare as to be practically non-existent, and the good general condition of the children is, we believe, partly due to their being ordered to have a light breakfast two hours before attending. This procedure may now appear old-fashioned, but it has given complete satisfaction to all concerned in what is by now a very large number of cases.—We are, etc.

E. CLAUSEN, L.D.S.

### Administration of Pentothal

SIR,—There has been much correspondence and controversy over the use and dangers of pentothal anaesthesia. In the coming months many thousand intravenous anaesthetics will have to be administered by practitioners who may not be familiar with their use. While no rule of thumb can ever be devised in medicine which will cover all cases and relieve the doctor of the duty of using his judgment in the individual case, yet general rules can be of great value if adhered to with proper discrimination. To the occasional anaesthetist a following rule seems to me of great value as it allows for a considerable margin of safety, even if the whole dose is injected fairly rapidly: always use the small ampoule (0.5 g.) of pentothal. Forget that the large ampoule (1 g.) exists—I am, etc.

### Tumour of the Breast treated with Stilboestrol

SIR,—The remarkable improvement in a case of scirrhus treated by stilboestrol has encouraged me to send you some notes on the case.

The patient, Mrs. X., aged 90, first noticed a lump in the outer segment of her left breast in April, 1940. When I saw it at this time it was about the size of a golf-ball, hard and irregular in shape, and devoid of pain. A chain of enlarged and hard glands

ran along the outer border of the pectoralis major muscle and merged into a similar clump in the axilla.

It was not considered desirable, on account of her heart condition and her age, to resort to any surgical treatment, and until Dec., 1943, little or no notice was taken of the lump. About this time the patient noticed that she experienced some "soreness" on pressing her arm into her side, and on examination I found a slight enlargement in the size of the tumour, and, although the skin was not involved, there was a dark purplish mushroom-shaped patch of discoloration over the tumour.

On Christmas Day, 1943, treatment by stilboestrol was begun. The dose was one tablet of 0.5 mg. thrice daily. In five days the pain caused by the pressure of her arm had disappeared and the lump itself gradually became smaller. Her general health has improved, and to-day the tumour is about the size of a small walnut, and, with the exception of a solitary gland the size of a nutmeg at the apex of the axilla, this region is free of glands.—I am, etc.

I. DOUGLAS BROWN, M.D.

### Metatarsalgia

SIR—In these days when millions of men and women are standing and walking more than they ever did before, the treatment of such a disabling complaint as metatarsalgia is of great importance. So far as standard works of medicine are "surgery" go, the teaching on aetiology and treatment has not changed materially in the last twenty years. The condition is supposed to be due to a neuritis of the digital nerves brought about by their being rendered vulnerable to pressure through the collapse of the anterior transverse arch of the foot.

Treatment is directed towards strengthening the muscles that are supposed to brace the transverse arch of the foot, strapping and taping the metatarsals for the same purpose or by a metatarsal bar which carries the weight further back. All who have had to employ these methods must have found them singularly ineffective. The reason for this is that the existence of an anterior transverse arch of the foot is a piece of anatomical fiction, based on the study of compressed and distorted shoes. It is not apparent in young children, nor, indeed, in any adult who habitually goes about in shoes. Study of the foot and method of walking of the barefooted African brings to light the following points:

(1) The foot at the line of the heads of the metatarsals is flat in pronation.

(2) All the toes are capable of doing plantar flexion so that the knuckles stand out prominently. This is most marked in the hallux, and is only slightly less so in the 2nd, 3rd, and 4th toes.

(3) In walking the foot does not passively roll forward on the metatarsal pad, but, as the body passes the vertical, the toes flex strongly, taking much of the weight off the metatarsals so that the pad which bears the thrust of the stride includes the pads of all the toes, particularly the 1st, 2nd, and 3rd, as well as the metatarsal pad.

(4) A study of the tracks of a barefooted walker in soft ground shows by the deep impression of the toes how strongly they engage in the act of thrusting the body forward.

In every case of metatarsalgia that I have examined, plantar flexion of the toes is absent or greatly diminished. When the condition is unilateral the power of flexion on the sound side is always markedly greater than on the affected side. When a step is taken off the affected foot the whole thrust of the stride is borne by the metatarsal heads and the overlying pad. It is not surprising that the nerves suffer from pressure, particularly as the weighted foot rolls forward on the metatarsal heads, contributing a grinding action to the weight effect. As in all foot deformities, the tolerance of the individual to an abnormal state differs widely, so that metatarsalgia appears in one individual when the condition is only slightly developed, while another will tolerate a much greater degree of deformity.

**Treatment.**—From what has already been said it will be clear that the treatment of metatarsalgia should be directed towards recovering the power of flexion in the toes and towards re-education in the proper use of the toes in walking. (1) The patient should be directed to plantar-flex his toes repeatedly at the metatarsal heads in such a manner that the heads are lifted clear of the ground; this simple exercise can and should be done at any odd moment such as when standing waiting for a bus. (2) He should be instructed to kick off with his toes at each stride and not let the toes bend up passively; this has to be done consciously at first, but becomes a habit later. The metatarsal bar is contraindicated because it leaves

the toes more helpless than ever, and other pads and straps have a similar adverse effect. Fortunately it is possible for the toes to recover their mobility after a great many years, and I have had successes in cases of 10 and 15 years' standing where the patient was intelligent and persistent.

I have no doubt that I shall be accused of over-simplifying this problem, and of failing to take into account the factor of the short and mobile first metatarsal (J. D. Morton, 1935); but here I am concerned only with aetiology in its relation to treatment, and treatment based on this simple aetiology works.—I am, etc.,

Luanshya, N. Rhodesia.

A. C. FISHER, M.D., F.R.C.S.

### The Colonial Medical Service

SIR.—I have read with appreciation the spirited reply of Dr. J. B. Davey (May 6, p. 636) to the uncomplimentary and unwarranted statement made by Dr. H. B. Morgan in the House of Commons on the Colonial Medical Service. Coming at such a time, when a large proportion of its members are, or have been, serving their country and our cause, these accusations would seem singularly ill-timed and inappropriate. Several, like those fine investigators Dr. E. C. Smith of Lagos and Dr. N. A. Dyce Sharp, have lost their lives by enemy action, and many others have been maimed in health as the result of this war. I myself feel such accusation keenly, for both my sons entered for this career and subsequently saw service in East Africa and Abyssinia. Perhaps it is not generally appreciated that Sir Patrick Manson played a great part in the development of the Colonial Medical Service, and took justifiable pride in its achievements. The medical world well knows that his great discoveries in tropical medicine some forty years ago were made with the willing co-operation of Dr. Ozzard, Dr. C. W. Daniels, and the late Sir Thomas Stanton, all of whom were members of this service.

More recent achievements in the field of medical science deserve mention: the pioneer work of Dyce Sharp in Nigeria on the transmission of the filaria (*Acanthocheilonea perstans*) through the minute midge *Culicoides*; the self-sacrifice of J. F. Corson in experiments during which he inoculated himself more than once with the deadly *Trypanosoma rhodesiense* in Tanganyika; the entirely British work on the control of sleeping sickness in West and East Africa from the time of Sir David Bruce onwards culminating in the large-scale preventive measures by Dr. H. M. O. Lester and Col. G. Maclean; work on the ecology of trypanosomiasis in East Africa and its relation to animals by Dr. Lyndhurst Duke; the classical researches of Drs. N. Kingsbury and R. Lewthwaite on tropical typhus in Malaya; investigations on yellow fever on the Gold Coast, which resulted in the death of Dr. W. A. Young from that dire infection in 1929. These are but a few examples among many which go to demonstrate that the Colonial Medical Service is not lacking in enthusiasm, energy, and originality. Like other medical services, it looks forward after the war to reorganization and expansion of its scientific activities, but popular attitude towards this noble service would be fortified by better-informed appreciation of Colonial policy in general. This would prove a source of satisfaction to many locally appointed medical officers and nurses, whose loyalty is unquestioned, to whom such damaging statements must be extremely baffling and discouraging.—I am, etc.,

London W 1

PHILIP MANSON-BAHR.

### Service Medicine and State Medicine

SIR.—The proposals for a State medical service before us and the possibility that an attempt may be considered to model any new civilian service on that existing in one of the Services make this lively and topical question of Service efficiency, or lack of it, of paramount importance to all sections of the profession. From recent discussions at medical gatherings, correspondence in the Press (lay and medical), and personal communications received, it is evident that widespread interest has been aroused, and it seems only just that this subject should be fairly and honestly examined from all angles. Might I therefore ask for the hospitality of your already overtaxed columns to touch briefly on some of the salient points as they appear to me.

Quite recently it has been stated that "Service patients... get better medical attention and after-care than do individuals even in peacetime." Doubtless a controversial statement, immediately open to criticism, but cannot be fully examined here. It would seem fair, however, to say that after almost five years of war the standard should at least be equal to that found in civil practice. In fact, if it was not so, surely it would be a grave reflection on the efficiency of our civil medical practitioners, who, after all, as civilians in uniform, now constitute the greater part of the personnel of the three fighting medical Services, and, further, many of these to-day hold some of the key administrative posts in these Services. Since the outbreak of war the Services have acquired the necessary equipment, and now also possess the administrative organization, but those of us who have spent some time in uniform know only too well how initiative and ambition are cramped and how the regular officer with his acquired "Service mind" is decried. Many now serving will be only too glad when they can return to civil practice. On the other hand, there are quite a number of both junior and senior officers who will prefer to return to some form of State service run on military lines, in which they can, for a time at least, find a haven of rest with freedom from care and want.

Certain officers in the R.A.F. Medical Service have found it necessary to repudiate criticism of efficiency in the Services as presented in the Press, and at some length have defended what they appear to regard as the Utopia of medical organization. To those who may not agree (and there are many) the inference is that they should stand aside and remain outside the new State service when it arrives. Now this view may have a large measure of truth in it regarding conditions to-day, but for my present purpose I cannot fully analyse it here. Personally I have the highest respect for the present direction of the R.A.F. Medical Service, and acknowledge the high qualities of the new Director-General, his abilities of organization and administration, with that laudable quality of approachability that has been extended to even the most junior ranks in the Service when some suggestion or criticism receives sympathetic consideration. Nevertheless, there must have been a great reversal of policy, planning, and thinking within recent times, since the policy of a few years ago in the R.A.F. was, "No more specialists in the R.A.F." It is common knowledge that certain officers have preferred to leave this Service on a variety of pretexts and return to civil life during the present war.

As one of those who voluntarily resigned from this Service after some months of duty I have first-hand knowledge of some of the inconsistencies and misdirection of talent that existed at that time, and it seems proper at such a time as the present that these irregularities should be made known, so that a balanced opinion concerning Service organization can be reached. Chief of the anomalies was that as consultant radiologist and specialist in radiology (in uniform) I was detailed to sit on medical boards as president or as a member to assess other people's diagnoses, including that of senior consultants and surgeons. There was no real shortage of general medical officers at that time, nor lack of x-ray investigations, but the latter had to be deferred until after board duty time. It was even suggested that the administration of anaesthetics came within the province of the radiologist, and some had to be given, but when warned of the possibility of performing an appendix operation the authorities were informed quite firmly that "all the wild horses," etc., would never induce even a radiologist to adopt such homicidal procedure. My original recommendations for the introduction of mass miniature radiography into the Service in 1939 were only just saved from the pigeon-hole by the timely gift of a motor mobile mass radiographic unit (the first in the country) from the British Red Cross.

Therefore it would appear highly important when we are thinking in terms of a new comprehensive medical service that those who were responsible for such chaos of administration and misdirection (some now retired) as I have touched upon are never allowed to drift on to such committees as the proposed Central or Local Health Services Councils, Joint Authority, or other bodies. Further, it becomes equally important that the Minister of Health shall not have the sole right

in the selection of his entire personnel for these committees, but that the voice of the doctor, consultant, and specialist must be heard and the profession seek the right to nominate and elect at least half or more of the members who shall serve on these committees.—I am, etc.,

London, W.1.

NORMAN P. HENDERSON

### Work of M.R.C. Committees

SIR.—The excellent account of the work of the Therapeutic Trials Committee of the Medical Research Council which is given in the current number of the *British Medical Bulletin* by a member of the staff of the M.R.C. arouses some important reflexions. First, it is not so clearly admitted, as would be both generous and relevant, that in this country drugs have been accurately tested by doctors and others for centuries before the Therapeutic Trials Committee was instituted, recent examples being the value of insulin, of liver extract, and of antipneumococcal serum, so far as their use in this country is concerned. Perhaps it is this bashful attitude towards the work of other people that is the cause of the misleading sentence with which the *Times* (May 11) commenced its leading article on this matter. "In this country," says the *Times*, "machinery for establishing, independently of the manufacturers, that a drug is free from danger and effective for the purpose for which it is designed has only been set up within recent years." Machinery in the form of semi-Governmental committees may have been lacking, but very good means for the same end were most demonstrably not, and the real advantages of the new machinery must not hide from us some of the risks which have already (though perhaps unknown to its historian) come to light.

For example, in an unofficial correspondence with a senior medical administrator it was stated to me that certain instructions on treatment were issued to doctors on the authority of a committee of the M.R.C. In replying to this dangerous form of excuse I stated that "findings of the M.R.C. committees can have no more authority than is given to them after they have been compared with all other sources of information available to the profession." The committee concerned was not the Therapeutic Trials Committee, but this shows the danger that exists of bureaucrats using committees of the M.R.C. as supports for what they want to do or obstructions to what they want to prevent. It would help to preserve the well-merited high reputation of the M.R.C. if it would tell the profession that it will welcome exposure of any effort to misuse its reports in such a way.

Another way in which committees of the M.R.C. can unintentionally do harm is if it becomes the habit, in subjects which they are known to be studying, "to leave it to the M.R.C." Groups of people who work together by written correspondence and occasional meetings, as members of such committees do, frequently miss the side-turnings in a subject that lead to new territory, and for this reason alone it should be very clearly acted upon that the M.R.C. adds to the effort for studying any subject, but its activities do not restrict the right of any other person to work on the same subject in any way available.

My contention, then, is that the M.R.C. committees can remain the useful and respected bodies that they are so long as there is no risk of their acquiring exclusiveness or of their results being misused by medical administrators.—I am, etc.,

London, W.1.

J. M. ALSTON

### Dental Hygienists

SIR.—In an article of mine in another journal, ("Teeth and Indigestion," *Practitioner*, April, 1944) I advocated the use of dental hygienists as an integral part of an efficient dental service. In this article I referred to the successful scheme of dental hygiene now being carried on in the Royal Air Force as well as to my part in an attempt to introduce this service in civil (charitable) practice in 1929. My remarks have brought many inquiries respecting the training of dental hygienists, their uses, and the objections to them. I wonder if you could possibly find space for the replies to some of these questions?

1. Dental hygienists (in comparatively small numbers, however) have been used in the U.S.A. for many years in private as well as

public health practice. They were recommended as indispensable by Fones as long ago as 1905. I have no record of their having been used in Great Britain or other European countries.

2. The Dentists Act of 1921 permits the employment of dental nurses for giving minor dental treatment in the public services, but forbids it in private practice.

3. Board of Education Circular No. 1279, 1922, prescribes how such dental nurses shall be used in the school dental service.

4. In 1930, upon the assumption that the term dental nurse might properly be regarded to include women trained essentially for administering prophylactic treatment—i.e., scaling, polishing, and examining for caries—and for instruction in oral hygiene, a dozen women were trained in University College Dental School, according to a syllabus which was drawn up for the purpose. The course occupied one year, and those who finished were employed in one or another form of public service.

5. So much objection was raised by dental practitioners, who feared that without more defined control there was a risk that unqualified dental practice might again creep in, that no further hygienists were trained.

6. A more selfish objection still sometimes voiced by uninformed members of the dental profession that dental hygienists would take away their practice is silly and untenable. For 16 years I have employed as hygienist in my private practice a qualified woman dental surgeon (as by law I cannot use anyone not fully qualified). I can only say that far from taking practice away she has invariably kept me very busy, while at the same time taking over a good deal of straightforward cleaning which many patients regard as somewhat minor in degree, though of recognized importance.

7. The experience of every busy dental practitioner is that his time is totally absorbed in fillings, extractions, and other major work, and that he has very little time left for prophylactic attention. Furthermore, the public generally is not yet sufficiently educated in preventive medicine to be willing to pay for advice only. "He did nothing, he only talked," is often the discouraging dismissal of invaluable instruction.

8. Those competent to judge suggest that in civil life, and in the case of women not previously experienced in dental work, one year or even eighteen months would be required for the training, especially if the hygienists were required for the care of children, thereby necessitating adequate instruction in diet and nutrition.

9. The present grave shortage of dental practitioners has given an opportunity for the Royal Air Force as I have explained in my article, to test the value of hygienists in their already very efficient dental service. Great credit is due to the Director-General of Medical Services, the Director of Dental Services, the Consulting Dental Surgeon, and the other dental officers who have made this successful experiment, which has now been in practice for the past 18 months and is being extended.

10. Everyone who has seen these hygienists giving treatment and instruction has been greatly impressed with the assured touch, the astonishing results of the technique, and the wisdom of the advice which they give to their patients.—I am, etc.,

London, W.1.

C. BOWDLER HENRY.

## Obituary

NORMAN HOWARD PIKE, who died at 6, Charlton Park Gate, Cheltenham, on Mar. 12, was consulting ophthalmic surgeon to the Herefordshire General Hospital, the Cheltenham Children's Hospital, and the eye department of the Cheltenham General and Eye Hospital, and was educated at Dulwich College and Guy's Hospital. He graduated M.B., B.S. in 1896 with honours in medicine and obstetrics, and then held the posts of house-physician and obstetric resident at Guy's. For ten years he was in general practice at Heckmondwike in Yorkshire, but as his interest in ophthalmic and oto-laryngological cases increased he gave it up and went to Vienna to work under Prof. Urbantschitsch in his clinic. On his return he was appointed surgeon to the eye, ear, nose and throat department of the Cheltenham General Hospital and continued so until he retired in 1942. He was a member of the B.M.A. for nearly 45 years. He was very much liked and respected by his colleagues, who regarded him as a most efficient and conscientious consultant whose advice could be relied upon: no operation, they knew, would be advised by him unless it was in the real interest of the patient, for medical men had become somewhat suspicious that the prevailing practice of wholesale tonsillectomies had not on the whole produced the results promised. Extremely careful in his examination he had a fine judgment and was a neat and deft operator. Always gentle and considerate in his treatment of hospital patients he was greatly missed by them when he retired. He had a pawky humour, with a Pikeian flavour of its own.

which was much appreciated by his friends. His favourite recreations were golf and cricket. He leaves a widow, two sons, and three daughters to mourn his loss; one of his sons is Cmdr B. Pike, R.N.

Dr. JOHN ARCHIBALD VALENTINE of Southsea, who died on March 27 aged 70, was consulting ophthalmic surgeon to the Portsmouth and Southern Counties Eye and Ear Hospital. Educated at Trinity College, Dublin, he had a brilliant career in classics and in medicine, and after taking his B.A., graduated M.B., B.Ch., B.A.O. in 1902, later proceeding to the M.D. and gaining the Cambridge diploma in tropical medicine and hygiene. For many years he was medical officer to tea plantations in India, where he acquired an intimate knowledge of tropical medicine and of ophthalmic work. In the last war he served with the R.A.M.C. in Salonika, and after the armistice returned to Southsea to devote himself solely to ophthalmology; he was on the visiting staffs of all the local hospitals as well as the Royal West Sussex Hospital, Chichester, and the Alexandra Hospital, Cosham, under the Ministry of Pensions. At the Annual Meeting of the B.M.A. at Portsmouth in 1923 he was secretary of the Section of Ophthalmology. His junior partner was mobilized in the R.N.V.R. on the outbreak of this war, and owing to the shortage of ophthalmic surgeons in the Portsmouth area Dr. Valentine immediately resumed full duty, and was in active practice till a few hours before his death. He had a wide knowledge of men and affairs. Outside his family and his professional work the great love of his life was sailing, and at the time of his death he was vice-commodore of the Portsmouth Sailing Club and rear-commodore of the Royal Portsmouth Corinthian Yacht Club. He is survived by his wife, the daughter of a well-known Dublin medical teacher, Prof. Walter Smith, and by two daughters. In the words of a colleague: "By the death of 'Archie' Valentine Portsmouth has lost a skilful ophthalmic surgeon and the medical profession a most valuable friend and colleague. . . . To those who knew him intimately the outstanding feature of his character was courage, at no time more marked than when he lost his only son near the end of a promising career at Sherborne."

News has just been received of the death in Singapore, in December last, of CUTHBERT STANLEY. Stanley joined the medical school of St. Thomas's Hospital in 1921 and qualified five years later, graduating M.B., B.S.Lond. in 1928. His early interest in ophthalmology he never lost, and he held the posts of ophthalmic house-surgeon at his parent hospital and at Moorfields. Following on a decision to work abroad he took the D.T.M.&H. and joined the Malayan Medical Service, in which from all accounts he served with considerable distinction. Stanley was always of a most cheery disposition. His heart was in his work, but he never would give himself credit for any good he might have done. He was a good doctor for he understood his patients, and it is typical of him that we heard that of his own free will he elected to stay behind to look after his sick countrymen rather than to try to make his escape. His many friends will lament his going.—A. J. W.

News has reached his daughter in this country, through the Red Cross, of the death in April, 1944, of Dr. FRANÇOIS CALOT at his home in France, Château de Miramont, par Pierrefitte-Nestalas, Hautes-Pyrénées, aged 82. Dr. Calot was a leading figure in the world of orthopaedic surgery and for many years carried on his work in hospitals at No. 69, Quai d'Orsay, Paris, and at Berck-Plage, Pas de Calais. His famous book *Orthopédie Indispensable* was translated into English by H. A. Robinson under the title *Indispensable Orthopaedics*, and ran into several editions.

## The Services

### CASUALTIES IN THE MEDICAL SERVICES

Wounded.—Major R. P. Howard, R.C.A.M.C.

Died of wounds in Burma.—Capt. C. J. Gannon, R.A.M.C.

### DEATHS IN THE SERVICES

Wing-Comdr. GEORGE WILLIAM PATON died on April 24, aged 43. He studied medicine at Liverpool University and qualified M.B., B.Ch. in 1926. After holding house posts at the Northern Hospital, Liverpool, he was appointed to a commission in the Medical Branch of the Royal Air Force on Oct. 2, 1928. He was serving as deputy principal medical officer (hygiene) at an R.A.F. headquarters overseas.

## Medical Notes in Parliament

### Vitamins to Occupied Europe

On May 9 Mr. HARVEY asked the Parliamentary Secretary to the Ministry of Economic Warfare whether the additional vitamins, for which permission had been given by the Allied authorities, were now reaching the civilian sufferers in the countries occupied by Germany. Mr. FOOT said that the first consignment of vitamin D preparations, the gift of the British and the Dominions Red Cross Societies, was now on its way to Geneva.

On the same day Mr. FOOT informed Mr. Hutchinson that he had considered the copy of a resolution, passed by a number of ministers of the Free Churches in Ilford, urging the Government to reconsider their policy concerning the supply of limited quantities of vitamins and milk concentrate for children and nursing mothers in certain countries, subject to the requisit assurances on control being obtainable. While the Government had every sympathy with the desire to relieve distress in enemy occupied countries, they remained of opinion that the advantage, direct or indirect, which the enemy would derive from any relaxation of the blockade would outweigh the advantage to our friends. Moreover, there would in the near future be strong operational objections to projects of this kind.

### Malaria Control Measures in West Africa

In the House of Lords on May 16 the DUKE OF DEVONSHIRE informed Lord Teviot that the prosecution of antimalarial work was constantly being undertaken by the West African Governments, but war conditions necessarily involved a substantial reinforcement of this work, particularly in regard to shipping and Service personnel. At the request of the Colonial Secretary, Prof. Blacklock, of the Liverpool School of Tropical Medicine, visited Freetown in 1940 to examine and advise generally on the adequacy of the antimalarial measures being undertaken there. The Liverpool School had a special interest in this work, and at one time Prof. Blacklock was in charge of the Sir Alfred Jones Research Laboratory at Freetown. He reported to the Colonial Secretary in 1941, but many of the recommendations he then made had already been acted upon. Prof. Blacklock had recently returned from a second visit to West Africa, where he had again surveyed the antimalarial measures in progress, and had examined the work which had been carried out since his previous visit. Although it had not yet been possible for him to submit a report he was understood to be satisfied that a great deal had been done by both the civil and military authorities, and that the position in regard to the occurrence of malaria had much improved. Dr. Bruce Wilson, of the Rockefeller Foundation, was also at present visiting West Africa, and would be given every opportunity of seeing and commenting on the antimalarial measures in force there in the light of his own experience as chief officer in the Foundation's recent campaign in Brazil to eliminate the anopheles mosquito, which was also the predominant species in West Africa. For nearly two years a special investigation, financed by a grant from United Kingdom funds, had been proceeding in regard to this mosquito in British Tropical Africa, with particular reference to methods of control.

**Experiments on Animals.**—Mr. HERBERT MORRISON, replying to Mr. Viant on May 9, said that the published return for 1939 showed that the total number of experiments performed on living animals in that year was 954,691. A large number were almost wholly simple inoculations and similar procedures performed either on behalf of official bodies with a view to the preservation of the public health or directly for the diagnosis and treatment of disease. The figures for the next three years were: 1940, 889,677; 1941, 764,013; and 1942, 932,448. The figures for 1943 were not yet available.

**Drug and Vaccine Needs of India.**—On May 11 Mr. AMERY stated that India produced her own requirements of cholera and typhoid vaccine. Between Nov. 1, 1943, and April 1, 1944, 6,900,000 cholera inoculations were given in Bengal. All demands of the Government of India for mepacrine, sulphonamides, and emetine for civil purposes had been met. Mepacrine was used in hospitals and dispensaries, releasing quinine for general use. Sulphonamides and emetine were similarly available in hospitals and dispensaries. Prices measures had been taken to deal with

**Silicosis Medical Board Examinations.**—Mr. HERBERT MORRISON said on May 11 that applications from miners in West Wales to the Silicosis Medical Board for certificates between Jan. 1, 1943, and April 30, 1944, were 2,440. The number of certificates issued was 625 and of those refused 663. At the end of April 1,152 cases

awaited examination or decision. Everything was done by the staff of the Medical Board to deal with cases expeditiously, but the claims on the medical profession at present made it very difficult to secure qualified men who could devote time to this work.

**Smallpox Vaccination in Dorset.**—On May 16 Mr. LEACH asked the Minister of Health whether he was aware that people in the Sherborne and other areas of Dorset had suffered from vaccination urged on the public by medical officials in consequence of the alleged case of smallpox, the diagnosis of which had not been confirmed; and whether he would issue to all medical officers of health a copy of his statement of policy under which he had recommended that school children and young adults should not be primarily vaccinated unless they had been in personal contact with virulent smallpox. Mr. WILLINK replied that he was aware that persons who were vaccinated did not in all cases escape ill effects; but he could not adopt the suggestion in the second part of the question. The statement to which Mr. LEACH referred, contained in a circular issued to qualified the recommendation alluded to smallpox prevalent in this country retains which did not apply to the most recent.

Mr. LEACH also asked the date on which reported to be suffering from smallpox entered hospital; whether she was still there and, if not, the date on which she left the hospital; how long she had spots before the investigation was made; how many doctors were engaged in the investigation; whether they made the diagnosis of smallpox which was not confirmed; and whether doctors from his Ministry examined the case. Mr. WILLINK said that the patient was admitted to hospital on April 1, and was discharged on April 20. She had spots on March 28 but was not able to visit her doctor until two days later. Nine doctors were concerned in the investigation of the case, including three of his medical officers. The opinion reached by six of them that it was a case of smallpox was not shared by two of his officers; but the precaution was taken of treating it as a case of smallpox. Occasionally the diagnosis of smallpox presented great difficulties and there was ample room for differences of medical opinion. At least three of the local doctors who judged this case to be one of smallpox were practitioners with substantial experience of the disease.

#### Notes in Brief

Mr. Willink stated in the House of Commons on April 18 that 16,319 doctors were under agreement with the insurance committees in England and Wales on January 1 last.

The Medical Research Council, to which Mr. Willink referred the claim made for "H 11" in the treatment of cancer, takes the view that as this preparation has been available to the medical profession and has been widely tried no action on its part is necessary.

Dr. C. H. Hampshire has been added to the members of the Penicillin Clinical Trials Committee appointed by the Medical Research Council.

In the first 12 weeks of this year approximately 13,350 cases of tuberculosis were notified in England and Wales. Figures for equivalent periods in 1943 and 1942 were approximately 13,000 and 12,100.

Mr. Churchill states that since Oct. 1941, £3,047,725 has been spent through British charitable organizations on surgical and medical items for Russia and on clothing. The public has contributed some of the funds for these supplies. In addition His Majesty's Government has made a grant of £2,500,000 for clothing.

It is estimated that about 30% of the population of rural districts live in houses which are not connected to or within easy access of a water main.

Mr. Johnston has stated that he does not intend to introduce legislation to amend the Milk and Dairies (Scotland) Act, 1914. He is satisfied with the present legislation under the Act.

## Medical News

The following have been elected Honorary Fellows of the Royal Society of Medicine: Prof. E. D. Adrian, O.M., F.R.S., Sir Farquhar Buzzard, and Sir Walter Langdon-Brown (Great Britain); Major-General Paul Hawley, Col. J. C. Kimbrough, Col. Elliott C. Cutler, Prof. E. B. Krumbhaar, and Dr. D. P. O'Brien (U.S.A.); Sir Ali Ibrahim Pasha, Hon. F.R.C.S. (Egypt); Médecin Général Inspecteur Adolphe Sicé (France); and Col. Johan Holst (Norway).

Prof. L. P. Garrod will give a lecture, arranged by the Polish Medical Association in the United Kingdom, on "The Principles of Modern Chemotherapy, with Special Reference to Penicillin" on Tuesday, May 30, at 5 p.m. at B.M.A. House. Visitors, including senior students of all London medical schools, will be welcome. The lecture will be followed by a discussion.

At the Royal Institution, 21, Albemarle Street, W., on June 2, at 5 p.m., Sir J. C. Drummond, D.Sc., F.R.S., will give a Friday evening discourse on the Hot Springs Conference and its bearing on nutrition in Great Britain.

The British Institute of Philosophy announces that Prof. H. H. Price (Wykeham professor of logic in the University of Oxford) will give a lecture entitled "Two Theories of Perception" at University Hall, 14, Gordon Square, London, W.C., on Friday, June 2, at 5 p.m. Cards of admission may be obtained free of charge from the Director of Studies at University Hall.

Prof. R. J. A. Berry, M.D., F.R.S.E., is to address the Royal Society of Edinburgh on Monday, June 5, on "Some Recent Advances in the Study of the Brain as the Implement of Mind."

The Harveian Lecture will be delivered before the Harveian Society of London on Monday, June 5, at 4 p.m., at the Royal College of Surgeons, Lincoln's Inn Fields, by Surgeon Vice-Admiral Sir Sheldon Dudley, Medical Director-General of the Navy. His subject is "State Medical Service Problems in the Light of Royal Naval Experience."

At the next meeting of the History of Medicine Section of the Royal Society of Medicine, on Wednesday, June 7, at 2.30 p.m., the following will speak: (1) Sir Arthur MacNalty, paper on "Edward Bancroft, M.D., F.R.S., and the War of American Independence"; (2) Dr. H. P. Bayon, note on "John Zephaniah Holwell (1711-98) and the Black Hole of Calcutta."

By arrangement with the University of Cambridge the Medical Research Council has established a Unit for Research in Applied Psychology at Cambridge. The unit is located in the University Psychological Laboratory, the head of which is Prof. F. C. Bartlett, F.R.S. Dr. K. J. W. Craik has been appointed to the Council's staff as director of the unit, and will have the collaboration or assistance of other workers there in the Council's service. The members of the unit will undertake work elsewhere than at Cambridge when required, including investigations within the field of the Council's Industrial Health Research Board.

Dr. Robert Ellis, who for three years has been vice-chairman of the Cambridgeshire County Council, has recently been elected chairman. Dr. Ellis has been chairman of the Cambridgeshire Insurance Committee, and from 1939-43 was president of the Cambridgeshire and Hunts Branch of the B.M.A.

Dr. Mary S. Stuart has been mentioned in dispatches in recognition of gallant and distinguished services in the Middle East.

The Pharmaceutical Society of Great Britain announces that five pharmaceutical manufacturers have each agreed to give scholarships to enable pharmaceutical graduates from China to take a two-years course at the University of London. They would then return to China to help to train the 50,000 pharmacists whom General Chiang Kai-shek requires for his ten-year plan for public health services. The donors of the scholarships are Allen and Hanburys Ltd., London; Boots Pure Drug Co. Ltd., Nottingham; Evans Sons Lescher and Webb Ltd., Speke, Liverpool; The Wellcome Foundation Ltd., London; and May and Baker Ltd., Dagenham. The idea of the scholarships was brought to this country by Mr. A. H. Bentley, son of the Mayor of Bolton, a pharmacist who escaped from the Japanese in Hong Kong. It is expected that the cost of each scholarship will be £1,400.

Nurses and domestic workers are to be medically examined before taking up duties in a tuberculosis institution, and generally the examination will be carried out by the staff of the M.O.H. for the area in which the candidate is living at the time. It will be a full clinical examination and include x-ray investigation and a Mantoux or similar tuberculin test. If there is any medical reason why the candidate should not be employed in a sanatorium the Ministry of Labour officer concerned will be informed. (Ministry of Health Circular 33/44.)

## Universities and Colleges

### UNIVERSITY OF CAMBRIDGE

As announced in a note in the adjoining column, the Medical Research Council has offered to establish a Research Unit in Applied Psychology in the University Department of Experimental Psychology. The department will benefit greatly from the establishment of such a research unit, and on the proposal of the Council of the Senate the Vice-Chancellor has been authorized to convey the thanks of the University to the Medical Research Council.

### ROYAL COLLEGE OF PHYSICIANS OF IRELAND

At a meeting of the President and Fellows of the College held on May 5 the following Members were elected Fellows of the College: T. D. O'C. Donelan, J. G. Gallagher, W. J. E. Jessop, J. K. McCollum, C. F. McConn, E. B. McEntee, M. J. O'Neill, Agnes Savill, S. Simms, R. C. Sutton.

A clinical meeting of the Whipp's Cross Hospital Medical Society was held at the hospital on May 12. After Dr. Goodhart and Dr. Sutton had read papers on diabetic coma and on appendicitis, Dr. Joseph presented seven cases to show the excellent results obtained by his modification of the Hey Groves operation for intracapsular fracture of the femoral neck. The patients were all between 65 and 75 years of age, and as a result of the operation showed no disability whatever. Dr. Joseph also demonstrated a case of burns due to methyl bromide vapour, and Dr. Sharp and Dr. Blond respectively showed cases of tabetic gastric crises and (?) blastomycosis improved by intensive potassium iodide therapy. Some 60 local doctors attended the meeting. At the next meeting, on Friday, June 2, at 8.30 p.m., Prof. S. P. Bedson, F.R.S., will address the Society on "Some Recent Work on Viruses."

The Central Midwives Board has re-elected Sir Comyns Berkeley as its chairman for the year ending March 31, 1945.

## EPIDEMIOLOGICAL NOTES

### Discussion of Table

In England and Wales during the week notifications of scarlet fever fell by 118, and those of diphtheria by 80. Dysentery notifications rose by 41.

Scarlet fever was less prevalent everywhere except in the Midlands. Yorks West Riding reported 58 fewer cases than last week. The figures for diphtheria were the lowest since last August. Whooping-cough notifications were 35 more than last week, the total being the highest for a twelvemonth. Although Hertfordshire reported a rise of 31 over last week's total, Yorks West Riding and Derbyshire had respectively 29 and 28 cases fewer. The notifications of measles were 20 fewer than in the preceding week, the total for the Isle of Wight mounting by 74. Kent and Durham, on the other hand, each reported 44 fewer cases.

For the fourth successive week there was a rise in the notifications of dysentery. The most important of the outbreaks were Shropshire, Atcham R.D. 45; Cumberland, Penrith U.D. 25; Derbyshire, Heanor U.D. 22; Northumberland, Newcastle-upon-Tyne C.B. 13; Warwickshire, Birmingham C.B. 11. There were 30 cases in London (Wandsworth 14), and 22 in Lancashire.

In Scotland measles notifications dropped by 105, those of whooping-cough by 54, and those of scarlet fever by 22. The total cases of dysentery were 12 higher than last week, and those of diphtheria 8. Argyll County reported 31 cases of this disease, and the cities of Edinburgh 20, and Glasgow 14.

In Eire the notifications of measles rose by 52 cases. The largest returns were Dublin C.B. 54; Dublin, Rathdown No. 1 R.D. 41; Cork C.B. 37; Waterford C.B. 34. Measles and whooping-cough are both said to be prevalent in Roscommon, but no figures are given.

In Northern Ireland scarlet fever notifications showed a rise of 16 over last week's total; 36 of the 82 cases were notified in Belfast C.B.

### Week Ending May 13

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,791, whooping-cough 2,548, diphtheria 584, measles 2,132, acute pneumonia 704, cerebrospinal fever 70, dysentery 280, paratyphoid 10, typhoid 8. One case of smallpox (a woman) was notified in Cheshire, Birkenhead C.B.

### Tuberculosis in America

The report issued by the New York Tuberculosis and Health Association shows that, despite a year of war, an improvement was registered in tuberculosis mortality in America between 1941 and 1942. The deaths in 1942 were 57,002, compared with 59,251 in 1941, and the equivalent death rates per 100,000 were 43.5 and 44.5. It will be remembered that in England and Wales a rise in tuberculosis followed the outbreak of war, the numbers of deaths for the years 1938-41 being 25,539, 25,623, 28,151, 28,667. The corresponding figures for Scotland were 3,432, 3,526, 4,003, 4,174. In New York City the death rate fell from 49.4 per 100,000 in 1941 to 46.2 in 1942, but there was an increase in incidence—9,834 new cases of tuberculosis were registered in 1942, compared with 9,222 in 1941. A gradual rise in notifications has occurred in England and Wales during the war, and both in America and in this country the upward trend is partly due to the earlier discovery of the disease by radiography. The coloured population of New York City had a mortality five times as high as the white population; the rates for 1942 were 194 and 42 per 100,000 respectively. The death rates in 1942 for the other American cities with a population of over a million were Detroit 45.0, Chicago 49.2, Los Angeles 54.4, Philadelphia 58.7, the differences from the 1941 rates being +3.8, -4.1, +0.2, +0.3, respectively.

## INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended May 6.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

### ANY QUESTIONS?

#### Coitus during Pregnancy

**Q.**—Is there any scientific evidence as a basis for giving advice on the harmlessness or otherwise of intercourse during pregnancy? Is there a risk of abortion in the early and/or late months? Authors seem to disagree, or give nebulous advice obviously not based on real evidence.

**A.**—It is obvious that coitus in the later months of pregnancy carries with it the risk of introducing pyogenic organisms into the birth canal. I know of no statistics bearing on the question of the possible influence of coitus on the incidence of abortion, nor is it likely that reliable figures could be easily obtained. Most gynaecologists suppose that, although in the majority of women no harm results, in a minority coitus will, directly or indirectly, irritate the uterus and so favour abortion: this is especially so in the first three months of gestation. As one famous teacher of a previous generation used to say: "One woman will go through a railway accident and suffer no harm, while her sister will abort at the smell of a badly snuffed candle."

#### Vaginal Discharge after Delivery

**Q.**—A patient aged 25 was confined 9 months ago. Since then she has had a profuse brown vaginal discharge. The puerperium was normal save that she was unable to feed her baby on account of scanty lactation. There was no obvious cervical damage and she has no other symptoms usually associated with retained placenta and chronic endometritis, etc. She has not yet menstruated again, she has always been irregular. General health is very good. It has been suggested that this discharge is due to an endometrial upset. If so, could you suggest any possible treatment?

**A.**—This type of discharge is not very suggestive of an endocrine upset. There are several more likely causes, and infection of the endocervix, cellular tissue, or even tubes is not necessarily excluded by the history of a normal puerperium. Other possibilities are erosion of the cervix, delayed involution with or without uterine retroflexion, uterine polypus, trichomonas vaginitis, and retained products of conception. I have recently seen a similar case in which the diagnosis proved to be tuberculous endometritis. The diagnosis can be established only by investigation. Determine first whether the discharge is really brown—i.e., blood-stained—or whether it is mucoid or purulent when fresh but dries leaving a brown stain on clothing. The discharge should be examined microscopically. If bimanual examination reveals no gross abnormality, inspect the cervix and vagina, using a well-lighted speculum. If the findings are still negative, the patient should be examined under general anaesthesia, the cervix dilated, and the uterus curetted. If there is any evidence of cervical infection, treatment with diathermy or cautery can be carried out at the same time. It is important to examine microscopically all material removed from the uterus; the diagnosis may ultimately depend on this examination. If there is any endocrine disturbance the sections should help to determine its nature and the appropriate treatment.

#### Points about Trilene

**Q.**—Is nitrous oxide-oxygen-trilene a safe anaesthetic to employ when the diathermy is in use in the neighbourhood of the face as, for example, in the operation for cure of detachment of the retina? Is there any danger of decomposition of trilene when kept over a period of weeks in a coloured bottle, as, for example, in the chloroform bottle of a Boyle's apparatus, in the operating theatre? Does any change occur in trilene when nitrous oxide and oxygen are passed through it?

**A.**—Trilene and oxygen can form an explosive mixture in certain circumstances; but these conditions are never likely to arise during

the administration of an anaesthetic. Nitrous oxide-oxygen-trilene may therefore be considered a safe anaesthetic to employ when the diathermy is in use. There is no danger of decomposition of trilene when kept in a coloured bottle over a period of weeks. The decomposition so far reported has been related to trilene passing over soda-lime. Two other factors are involved. First, the soda-lime had a high content of sodium hydroxide—11.5% as against 2.5% or less in some soda-limes. This allows the formation of heat, and a temperature over 60° C. accelerates the process. Secondly, economy was exercised and the soda-lime was kept, instead of fresh material being used for each anaesthetic. This allows time for the chemical reaction to continue. No change occurs when nitrous oxide and oxygen are passed through trilene.

#### Splitting of Finger Nails

**Q.**—What is the cause of the splitting in layers of the finger nails? Suggestions for the treatment of this condition would be welcomed.

**A.**—Splitting of the finger nails is sometimes due to nail varnish or to one of the skin hazards met with in ordinary housework. It may also be met with in systemic disorders such as hypothyroidism. Not infrequently no recognizable cause can be discovered.

#### Generalized Vaccinia

**Q.**—Two days after the successful vaccination on the arm of a baby aged six weeks, several vesicles appeared on different parts of the child's body, face, fingers, penis, sole of foot, etc. These vesicles had an inflamed base, contained turbid fluid, and closely resembled the original vaccination vesicle. What is their cause? Have they any connexion with the vaccination? Are they likely to leave scars?

**A.**—Although generalized vaccinia due to systemic spread of the virus is a very rare complication of vaccination, the description given here would conform to that diagnosis. Rashes after vaccination are not so uncommon, but they usually fall into the allergic group—e.g., papular or circinate urticaria, eczematoid eruptions, and erythema multiforme. All of them may be accompanied by much constitutional upset. Secondary vaccinal lesions due to auto-inoculation or to the contaminated fingers of an attendant may also occur, particularly if the patient is already suffering from some skin disease, and it may be difficult to distinguish auto-inoculation from generalized vaccinia. However, typical lesions appearing on inaccessible parts of a healthy skin would support a diagnosis of generalized vaccinia. The rash evolves in the same way as the primary vaccinal lesion and is likely to leave small pock marks.

#### Byssinosis

**Q.**—Could you instruct me as to the clinical features of byssinosis, together with treatment and prognosis of the condition? Should a workman who has had byssinosis continue to work in a woolen mill, and what effect would this have on his compensation rights?

**A.**—Clinically the physical and radiological signs of byssinosis are identical with those that occur in chronic bronchitis with emphysema; but in a case of byssinosis there is often a very suggestive history—namely, that a man previously free from chest symptoms, after working in a card-room for a number of years, complains of cough and shortness of breath which are always most marked on Mondays and improve as the week goes on; and by the end of the week he is tolerably comfortable. At first this cycle goes on week after week, until in the later stages he is affected almost equally on all days. There is no specific treatment for the condition, but some cases are benefited by breathing exercises. A man so affected should be advised to change his occupation before he is totally incapacitated.

Compensation for byssinosis is for total disablement for any gainful occupation, but before such compensation is granted the worker must have been employed in a card-room for 20 years or more. If at the end of this period he is admittedly suffering from byssinosis, employment in some other work would not interfere with the man's future rights to compensation. It would, however, on health grounds be inadvisable for him to work in a dusty atmosphere such as might be present in certain departments of a woollen mill.

#### Oestrogens and Cancer

**Q.**—I was taught as a student that oestrogenic hormones, if administered to a case of leucoplakia vulvae, would usually aggravate the condition and might precipitate a carcinomatous change in the lesion. Assuming this to be correct, I find it difficult to understand the rationale of the treatment of mammary and prostatic carcinoma with stilboestrol. Con the fact that, whereas oestradiol is a naturally occurring substance, stilboestrol is a synthetic product have any bearing on the subject?

**A.**—Leucoplakia vulvae should not be treated with oestrogens. Though there is no definite evidence that such treatment does harm it certainly does no good and may result in a dangerous delay before proper treatment is instituted. There is no rationale at present for

the treatment of mammary carcinoma with oestrogens. In fact in susceptible strains of mice oestrogenic treatment increases the incidence of carcinoma even in males. It makes no difference whether natural or synthetic oestrogens are used. This effect can be diminished or delayed by androgenic treatment. The carcinogenic principle is conveyed in the mother's milk, the function of the oestrogens being in all probability the development of the breast to an anatomical state in which it is susceptible to the carcinogenic substance. This is a colloid of high molecular weight, perhaps a virus. Thus in mammary cancer it is probable that the role of oestrogens is not strictly carcinogenic. On the other hand it seems likely that in other organs oestrogens may be carcinogenic. Malignant tumours of the uterus have been induced in mice in which the milk factor is absent. There is no definite evidence that oestrogenic treatment has ever induced malignant disease in humans.

The rationale of the treatment of prostatic carcinoma rests in the fact that the growth occurs in that part of the prostate which enlarges under androgenic treatment and decreases under oestrogenic treatment, and that prostatic cancer tissue strongly resembles normal tissue, especially in its function of producing acid phosphatase. The growth of both normal and cancerous prostatic tissue is inhibited by oestrogens, whether natural or synthetic. It does not follow, of course, that oestrogens are of use in senile enlargement, which does not affect true prostatic tissue but is confined to tissue which is vestigially female and is therefore increased in size by oestrogens.

#### Leeches and Malaria

**Q.**—Is there any truth in the belief that leeches can act as carriers of malaria in malarial districts?

**A.**—There is no evidence even suggesting that leeches can act as carriers of malaria, and it is extremely unlikely that they should do so. There is, however, the possibility that a leech might in special circumstances transmit infection by direct inoculation. It is well known that malaria can be conveyed artificially by inoculating infected blood, and instances are known where malaria has been transmitted by the use of a common syringe when inoculating a series of individuals with a drug intravenously. It has also been recorded in the case of drug addicts using a common syringe. It is therefore just within the bounds of possibility that a leech which has fed on a malaria-infected person might by direct transmission infect a second person. A much more probable origin of the belief referred to is that where there are leeches there are likely to be anophelids, and that attacks of malaria have been ascribed to the more obvious and spectacular attacks by leeches when in reality they have been contracted in the usual manner by the bites of anophelids of which the victim has taken little note.

#### Multiple Exostoses

**Q.**—A man aged 28 has suffered from exostoses all his life. Six large ones have been removed from his femurs and feet during the last eight years, and he is slowly developing two new ones on one femur and two on one arm. Can you suggest a suitable treatment?

**A.**—In view of the fact that the underlying pathology of multiple exostoses starts in infancy, there is clearly no radical prevention possible in adult life. The exostoses must be dealt with locally if they cause trouble. At the age of 28 no further growth of any extent is likely, though calcification of pre-existing chondromata may occur.

#### A Patient's Dilemma

**Q.**—A patient aged 40 has suffered since childhood from nervous diarrhoea which almost invariably affected him when he went to church. My request for advice may sound peculiar, but my patient is soon going to get married in church, and is extremely worried about "holding out" for the duration of the ceremony. What drugs are likely to be most effective in immobilizing the gut?

**A.**—This psychoneurotic symptom, apparently almost entirely limited to occasions of church-going, could very probably be eliminated by a short course of psychotherapy. However, as time is short, if recourse must be had to drugs I suggest the following: Tinct. opii 10 minims, ext. hyoscyam. liq. 6 minims, sod. phenobarb. 1/2 gr., cret. praep. 30 gr., mucilag. tragacanth. q.s., aq. chloroform. ad half ounce. to be taken on retiring the night before the wedding and after breakfast on the day of the wedding. If the marriage is arranged for the afternoon, a further dose must be taken about one hour before going to church. The mixture may do the trick but cannot be guaranteed to combat the effects of high-grade anxiety. The subsequent depression arising from these drugs might in a neurotic man lead to impotence, which would then be perpetuated by fear. This warning is necessary, because should such an event occur the patient's wrath would be visited on the doctor. Without the phenobarbitone it is doubtful whether the other drugs would act as sufficient check, but it is quite likely that they would do so and no appreciable effect on spinal nerve reflex would be produced.

## INCOME TAX

### "Pay as you Earn"

"BETA" occasionally does locum work for his former partners and for a local practitioner.

\*\* Presumably the earnings of "Beta" are assessed under Schedule D as professional profits, and the pay-as-you-earn system would be inconvenient. It cannot be said to be legally wrong to apply it, but it is thought that in general it will not be applied to locumtenents. It might be advisable in "Beta's" case, seeing that he knows for whom he is likely to act, for him to ask the inspector of taxes to authorize the practitioners concerned not to deduct tax from him, thereby removing any doubt there may be.

### Retiring Partner's Liability

A and B are partners on an equal share basis. A is retiring from the partnership on June 30, 1944, and B is taking in an assistant. How is the income tax due on July 1, 1944, apportioned?

\*\* The tax due on July 1, 1944, is the second instalment of the tax assessed for the year to April 5, 1944. As A was a partner during the whole of that year no apportionment is due. In fact A will be liable to account, in addition, for his share of the tax in respect of the period from April 5, 1944, to June 30, 1944, but that tax will not be due to the Revenue until the January and July instalments for 1945 become payable.

## LETTERS, NOTES, ETC.

### High Birth Weights

Dr. WALTER CALVERT (Stoekport) writes: Your contributor's answer under the above heading (April 8, p. 510) is the type which invites "I can beat that" letter. I have a patient in hospital now whose twins weighed 8 lb. 4 oz. and 8 lb. at birth. Both are breast-fed and both are well above their birth weights on the 12th day.

Dr. W. M. PENNY (London) writes: Several years ago I attended a lady who had twins weighing respectively 8 lb. and 9 lb. Fortunately it was her second confinement, so the births were not difficult. The first was a vertex, the second a breech.

### A Swallowed Button

Mr. E. J. WILKINS, editor of *British Plastics*, writes: My attention has been drawn to a letter from Dr. J. A. Stevens in your issue of April 29 (p. 610) regarding the detection of a plastic button by x rays. This is a very interesting case, but I think the inference drawn by Dr. Stevens in the last two lines of his letter is entirely wrong, and that the radiographer and not the composition of the button is responsible for the valueless x-ray examination. So far as I am aware, if the x rays are adjusted correctly there is no plastics material that will not show its presence. The fault seems to be with the radiographer who, it is admitted, showed no interest in the buttons on the coat given to him by the mother. I am writing merely to correct the inference of Dr. Stevens that plastics buttons may be dangerous on babies' clothing because if they are swallowed they cannot be detected.

### The Blocked Eustachian Tube

Dr. OCTAVIA LEWIN writes: The emphasis that Dr. Hilton Brown of Edinburgh (May 6, p. 635) lays on the fact that ear troubles are mostly due to infection from the pharynx stresses the need for close attention to the Eustachian tube and the danger of letting the opening get blocked. It is the only entrance for germs, and it is normally permanently open and so ensures no interruption in the sense of hearing. The exception to this is during the act of yawning, which causes its closure, but this is never more than momentary. The common cause for Eustachian deafness is the nasal obstruction that necessitates mouth breathing. Careful attention to the nasal toilet is therefore the best preventive against ear troubles.

### Osteo-arthritis of Hip

Dr. A. GORDON WATSON (Bath) writes: Your answer in the "Any Questions?" section under the above heading (April 29, p. 608) omits the value of treatment in hot mineral-water baths, especially of the pool variety. We find at the Royal National Hospital for Rheumatic Diseases that a large percentage of working men and women (miners, navvies, housewives, etc.) return to their work, and can continue working, for a year or more without further treatment, even when the x-ray films show marked osteo-arthritis of one or both hip-joints. If the improvement is not maintained for six or eight months the patient is advised to return at once for a further course of balneological treatment, and this method suffices for the majority. In some recalcitrant cases with severe pain, deep x-ray therapy is combined with balneological treatment, and is found to be successful in relieving pain in a considerable proportion of cases. The patient is often advised to continue remedial exercises at home plus a course of iodine internally in some form or other.

LONDON SATURDAY JUNE 3 1944

## SOME PROBLEMS OF INFECTIVE HEPATITIS

BY

L. J. WITIS, M.D., F.R.C.P.

*Nuffield Professor of Clinical Medicine, University of Oxford*

We might begin by asking ourselves what justification there is for regarding infective hepatitis as an infection at all, or for using this name in place of synonyms such as simple jaundice, catarrhal jaundice, or epidemic jaundice. Certainly none of Koeh's postulates has been fulfilled, and the history of nutritional deficiencies such as ergotism and scurvy shows that epidemicity is no criterion of infection. There is, however, the well-authenticated fact that people often go down with infective hepatitis approximately a month after contact with a case—often quite a brief contact; and the transmission experiments of Voegt (1942) and Cameron (1943) are hard to explain except by some sort of virus. Nevertheless, although infective hepatitis seems to be an infection, it has not been possible to transmit it to any experimental animal in spite of numerous attempts and modifications. There are no characteristic histological lesions such as inclusion bodies, and tissue culture has given no assistance. We are unable to recognize the virus except by human transmission, and there is no laboratory test for the pre-icteric or subclinical forms of the disease. Compare the position with Weil's disease, in which there is a visible organism, an animal host, and a sensitive serological test, and in which, as a result, the frequency of non-icteric and subclinical infection has been revealed, and it will be seen under what a disadvantage we labour.

It is important to consider this question whether "catarrhal jaundice" occurring sporadically or epidemically is an infection, because jaundice sometimes occurs after the injection of human serum or plasma, or during the course of treatment of syphilis with organic compounds of arsenic. The symptoms, biochemical alterations, and morbid anatomy of this homologous serum jaundice and of post-arsenical jaundice are very similar to those of infective hepatitis. In all three illnesses there is an acute hepatitis and the microscopical picture of the liver is identical. (In parenthesis it may be added that jaundice proved to be due to catarrh of the duodenum or bile ducts is excessively rare.) Nevertheless, it is doubtful whether homologous serum jaundice and post-arsenical jaundice are infectious or contagious, or transmissible in any way except by deliberate inoculation.

The incubation period of infective hepatitis is approximately 30 days, while that of homologous serum jaundice and post-arsenical jaundice is usually 60 to 90 days. It is possible that homologous serum jaundice and post-arsenical jaundice are one and the same disease, small quantities of serum being passed from one patient to another in the syringes used for the injection of the arsenic. The incidence of post-arsenical jaundice can be greatly reduced by scrupulous precautions to prevent transfer of material from patient to patient (Salaman,

1944). It seems improbable that the virus of infective hepatitis is the factor which is transmitted in inoculation jaundice. A virus should not require a longer period of incubation with injection than with natural infection. Moreover, homologous serum jaundice does not protect the individual from contracting infective hepatitis; in fact, it appears to increase his susceptibility to this disease (Gordon, personal communication, 1944). Although second attacks of infective hepatitis do occur, they are uncommon enough to suggest that an attack of infective hepatitis itself is usually followed by the development of immunity. Finally, there is no evidence that patients with homologous serum jaundice or post-arsenical jaundice ever infect their neighbours. This is not for want of opportunity, because both diseases have occurred on an unprecedented scale during this war. On the other hand, homologous serum jaundice can be transmitted to further subjects by inoculation, both during the incubation period and for at least a week after the onset of the jaundice (Oliphant, Gilliam, and Larson, 1943). These observations suggest that infective hepatitis is a different disease from homologous serum jaundice or post-arsenical jaundice, but they are not conclusive.

Obviously infective hepatitis is not a disease one would choose to study if one was out for quick results. Unfortunately it has proved one of the three most important diseases in the Mediterranean theatre of operations, the others being malaria and venereal disease. Disturbing features of infective hepatitis are the relatively long stay in hospital, the absence of any method of prophylaxis, and the steady rise in incidence in the four successive autumns of the war. On occasion it has interfered with military operations, and it has disproportionately affected key personnel such as officers and air crews. Coming at a time of year when malaria and battle casualties are also likely to be frequent, it imposes a heavy strain on medical facilities. The military authorities may well wonder what the incidence is likely to be next season, and public-health administrators are troubled by the risk of epidemics among the civilian population.

## Clinical Features

Infective hepatitis is characterized by a pre-icteric and an icteric stage. During the epidemics abroad a surprisingly high proportion of the patients have been admitted to hospital during the pre-icteric stage. The symptoms in this stage are quite unlike the picture of "catarrhal jaundice" which many of us had formed. The onset of the illness may be sudden, with high fever. Respiratory catarrh occurs in a small proportion of cases, though it is not certain whether this is part of the symptomatology of infective hepatitis or is due to a coexistent respiratory disorder. In other cases adenopathy is a feature, and the blood picture in the early stage may resemble that of glandular fever. More commonly, anorexia and alimentary symptoms are in the foreground. The dissimilarity between our mental image of infective hepatitis and its real appearance may have two effects: it may cause the observer abroad to

wonder whether the disease he is seeing is the same as occurs at home; or he may be tempted to try to classify infective hepatitis into different types. I shall not anticipate unpublished work further than to say that there is little doubt that it is all one and the same disease.

A major difficulty in the pre-icteric stage is the differentiation from clinical malaria—that is to say, an attack of malaria in which the parasites are found only with difficulty and after a prolonged search. There is sometimes a lull between the pre-icteric and icteric stages of infective hepatitis, and the patient is then apt to be discharged from hospital with the diagnosis of clinical malaria, only to return a few days later with jaundice. In general, anorexia suggests infective hepatitis and splenomegaly suggests malaria, but it is impossible to make the differentiation with certainty at the bedside, and a simple laboratory test for infective hepatitis would be an immense help. A further difficulty lies in the fact that a patient may suffer simultaneously from malaria and infective hepatitis, as is only to be expected from their frequency and their occurrence at the same time of year. Finally, jaundice may occur as a complication of malaria itself when the blood or the liver is damaged by the plasmodium. For all these reasons it is wise to play for safety and to treat the patient for malaria when the diagnosis is in doubt. The importance of early treatment of malaria is great. Many pre-icteric cases of infective hepatitis have been treated with quinine and mepacrine and have taken no harm thereby. Pamaquin, however, is probably undesirable if there is any suspicion of disease of the liver.

Little need be said about the icteric stage, for when jaundice appears both patient and doctor are usually out of the wood. It is of interest to mention that arthritis, skin rashes, urticaria, and conjunctivitis have all been noted in infective hepatitis, and we therefore cannot regard these symptoms as peculiar to homologous serum jaundice, though they are probably more common in that condition. An uncommon but even more interesting symptom is neuritis, either localized or generalized. It must be remembered that both mononeuritis and polyneuropathy are not infrequent in the Mediterranean theatre of war, and that there are few illnesses, medical or surgical, with which infective hepatitis has not at times been associated. We may therefore merely be dealing with the coexistence of two diseases. Nevertheless, similar nervous complications have been seen in this country, and we cannot avoid the suspicion that the virus of infective hepatitis may at times attack the nervous system.

Recurrences of jaundice are not infrequent, appearing in about 2% of cases. In most cases the relapse occurs within four weeks; of 21 relapsing cases, 2 relapsed a second time. The average stay in hospital in British troops is about 15 days, with another four weeks at a convalescent home. Only a very small percentage of cases have been ill enough to evacuate to the United Kingdom. The mortality among cases admitted to hospital is less than 1 per 1,000, and it is probable that a number of subclinical cases never reach hospital.

#### Duration and Treatment

There is no specific treatment of infective hepatitis. There is good reason to believe that recovery is accelerated by rest in bed and retarded by premature activity, and there is a strong conviction that patients take little harm from the amount of fat in the wartime diet, if they eat according to appetite. It may not be possible to provide special diets in the field, and the strict prescription of a fat-free diet may mean actual undernourishment of the patient.

It will probably be extremely difficult to prove the value of any special treatment, as the death rate is so low and the length of illness so variable. In a series of cases admitted to a military general hospital the urine was free from bile within seven days after admission in 15%, within ten days in 55% and within fifteen days in 75%. The coefficient of variation is therefore high even when an objective criterion of this kind is used. It is probably even higher when merely the duration of stay in hospital is measured. Stocks (1944) has analysed the records of 808 patients admitted from the Services to E.M.S. hospitals on account of jaundice. Although the commonest length of stay in hospital (including convalescent home or depot) was 14 days, the range of variation was very wide. A rough calculation from his figures shows that the

mean duration of illness was 40 days, with a standard deviation of 27 days.

To obtain convincing results from therapeutic trials it is necessary to treat a series of alternate cases and controls and to submit the figures to statistical analysis. A calculation based on Stocks's figures indicates that a treatment which shortened the mean duration of the illness from 40 to 30 days would require a series of 117 cases for the results to be barely significant and 263 cases for them to be highly significant. If, however, the treatment shortened the illness by one-half—i.e., from 40 to 20 days—the corresponding number of cases would be only 29 and 66. Carefully controlled studies of this kind are rarely possible under conditions of warfare, when staff is short and patients are liable to be transferred at short notice. On the other hand, it is hard to get enough cases to carry out preliminary trials of this order at home.

At present we do not know what is the amount of time lost from this illness in our Forces. It is possible that it may be unduly high among troops in an operational area, who may be transferred from one hospital to another owing to pressure on beds and may eventually land up far from their own unit. It should not be difficult to discover the facts by an appropriate statistical study, and, if the time lost proved to be excessive, consideration might be given to the formation of special units for the treatment of jaundice close behind the line, such as have been formed for the treatment of venereal disease. Such units would also enable us to get more accurate information than we have at present about the effect of treatment and rehabilitation on the length of stay in hospital and convalescent home and on the rate of relapse. There is evidence that the enemy keeps men with jaundice in the line as long as they are not completely incapacitated.

#### Predisposing Factors

There must be reasons why jaundice is more common in war than in peace and why epidemics occur in the autumn. These, however, can only be predisposing factors, for there have been many epidemics of jaundice in peacetime and in all seasons of the year. The agents commonly invoked are cold, strain, dietary changes, and intestinal infection. So far as cold is concerned, "chill on the liver" is a familiar if vague synonym for infective hepatitis, and I have commented on the coexistence of respiratory catarrh in some cases of infective hepatitis. There is a high incidence of jaundice in British air crews, who may be exposed to the cold of high altitude and in British officers, who, unlike the men, undress at night and sleep in pyjamas. Nevertheless the last epidemic began in the hot weather and declined sharply after the first frost of December. Neither American officers nor American flying personnel show an incidence above the normal, and in our own Air Force steps had been taken to prevent chilling when air crews had to fly at unaccustomed heights over Europe. Men of one armoured division, which had a high incidence of jaundice, were sleeping on camp beds in comfortable barns. Strain also appears an unlikely factor, for this particular division had been resting for three months, and the disease has occurred quite commonly in the back areas during this last year. The high incidence in certain combat troops may be a matter of place rather than of strain.

There is no evidence of any dietary or drug predisposition. It has been suggested that officers, who have had a much higher incidence of jaundice than the ordinary ranks, eat less carbohydrate than the men, but it would be ludicrous to pretend that the officers are suffering from carbohydrate deprivation. Suggestions of a deficiency of vitamins appear equally unfounded. Prophylactic mepacrine was administered on a large scale during the summer and autumn of 1943. Mepacrine is a potentially toxic substance, and there was some difficulty in securing tolerance for the drug when it was first administered but there is nothing to suggest that it had anything to do with the incidence of infective hepatitis. Large epidemics have occurred among troops who were not taking antimalarial drugs in Malta and the Western Desert, and there has been a high incidence among British air crews, who take quinine instead.

\* I am indebted to Major Arthur Jordan, R.A.M.C., for suggesting this calculation.

of mepacrine because it is believed to have less effect on altitude tolerance. There is no evidence that alcohol, arsenic, or sulphonamides play any part, and it is stated that there has been no corresponding seasonal variation in the incidence of post-arsenical jaundice. As for diarrhoea and dysentery, they have been unusually mild in the present war, and they are not more frequent than normal in the history of cases of infective hepatitis.

### Epidemiology

In discussing the epidemiology of jaundice there are two pitfalls to avoid. It is dangerous, when studying statistics from a large body of men such as a division, to assume that the experience of all its members has been uniform. If the statistics are analysed it will be found that no such uniformity exists, owing to the diverse movements and contacts of the individuals, and the losses and replacements of personnel. A unit which has been in a theatre of war for a year may contain less than half its original members; the remainder may be new-comers to the area. It is equally dangerous to assume that the epidemic of 1943 was a kind of influence or process which began in the middle of August and ended in January. Such influences may indeed exist, and it is true that the collected figures for a whole area or army form a smooth curve which extends over such a period. But when we break down the statistics into their component parts we find that the major epidemic is really the sum of a number of minor epidemics, which were by no means contemporaneous. In the present state of knowledge it would seem wise to base our opinions first on accurate study of these individual small epidemics.

Unpublished studies of this kind have now been made by a number of observers (Kirk, 1943; Spooner, 1943; Mallory, 1943). When a single unit is studied, such as a squadron of an air force or a body of troops living and working together, the pattern of the epidemic is not very different from outbreaks of jaundice in schools and similar communities at home. A herald case, then perhaps another at an interval of 1 to 3 weeks, usually 10 to 13 days; a similar interval, and then the epidemic, which rarely may be almost explosive in its intensity. The great bulk of the cases may occur within 14 days of each other, though usually they are spread over a longer period. I am not going to pretend that observers have agreed in their interpretation of these phenomena. The argument is whether they can be explained by the orthodox hypothesis of droplet infection or whether we must invoke some other mode of spread. To my mind the orthodox hypothesis is quite adequate. But my point at the moment is that this kind of analysis of concrete situations is the proper method of approach, and we should exercise great caution in drawing conclusions from crude data such as the general incidence of jaundice, flies, temperatures, etc.

Infective hepatitis may be localized in place as well as in time. The localization may sometimes be very precise, as in a series of cases occurring at approximately monthly intervals among people working in the operating theatre at a general hospital. Such an attenuated epidemic could very easily be explained by droplet infection, though it had also raised the possibility of infection via blood-contaminated hands. Commonly, however, localization is on a broader scale. In 1942 the Eighth Army bore the brunt of the attack of jaundice, and the incidence was heaviest in troops who had actually spent a week or more in the Alamein battle area. Though the incidence of the disease in Egypt rose considerably in Oct., 1943, it soon fell, and never reached the high levels of 1942 when the troops were in the Western Desert. The Americans believe that there has been less liability to jaundice in the Casablanca area than in Oran and Sicily.

There is no doubt, however, that the disease is endemic throughout the whole Mediterranean area. Cameron (1943) has already shown this for Palestine. Several better-class Egyptians with whom I talked spoke of their children having had jaundice. Dr. A. F. Zanaty told me that not only did he see the disease in private practice in Cairo but that there had been a small outbreak among Egyptians attending the King-Fuad Hospital towards the end of 1943; the age of the patients was 15 to 30, and the disease began with slight fever and respiratory catarrh. Moreover, severe cirrhosis which is

not due to bilharzia is not very uncommon in Egyptian children about 7 to 10 years old; some of this may be the sequel to infective hepatitis. In North Africa infective hepatitis is not infrequent in the French and Italian colonists. There is no information about its occurrence in the Arab-Berber population, but all that can be concluded from this is that there has probably been no major epidemic among them.

Although there is a local reservoir of infection, there have been some curious differences in the incidence of the disease in different elements of the Allied forces which have come to the Mediterranean area. The relative immunity of Indian and Maori troops has already been established. It has since been discovered that the relative incidence in white and coloured troops in the American forces is 10 to 1, though there is no difference in work or feeding habits. A contrast is provided by native Belgian Colonial troops brought to the M.E. Among these there were 216 cases of infective hepatitis, with 9 deaths. They are a primitive people who had previously mixed little with other races, and they have also suffered severely from mumps and chicken-pox. It is hard to imagine that a people could have an inborn susceptibility to three different infectious diseases, and these variations in racial susceptibility may well be acquired characteristics.

There is another variation in incidence which can hardly be explained by any inborn difference in susceptibility. This is the fact that officers in the British Army and flying personnel in the R.A.F. are four times as often affected as ordinary ranks and ground staff. The most popular explanation of this phenomenon is that it is due to a difference in feeding habits. The ordinary soldier lines up to receive his food in his individual mess tin, whereas officers and flying crews mess together and share crockery in common. It is therefore easier for infected crockery to circulate among officers and air-crews than among ordinary ranks.

A number of facts support this explanation. Officers and men were equally attacked last year in the New Zealand forces who were in the battle area, where officers may eat under the same conditions as the men. There is no difference in the incidence of infective hepatitis in officers, air-crews, enlisted men, and ground staff in the American forces. American officers more often eat with their men than do ours, using their own personal mess tin or can of food. Moreover, American dish-washing facilities have hitherto been better than ours, and officers' messes have followed the standard procedure, in which the utensils are dipped in water which is actually boiling, so that the risk of transferring infection by this route is minimized. In the British Army officers' cook-houses have not always been as strictly supervised as those of the men, and the level of hygiene has sometimes been inversely proportional to the rank of the mess.

Measures to improve the hygiene of washing-up should of course be encouraged. Too often the water is cold, greasy, and dirty, and the towels far from clean; soap is often in short supply, and however carefully the crockery is rinsed a film of grease remains on it. There is evidence that units who wash up with soapy water have less jaundice than those who do not, but I am not convinced that communal crockery is the essential cause of the high incidence of jaundice in British officers and air-crews. The Service man's knife, fork, spoon, and mug may well be contaminated during washing-up in the communal bucket, and the use of communal plates is very common, especially in more static units. Again, it is odd that warrant-officers and sergeants, who also have their own mess and communal crockery, do not have a high incidence like the officers. It is said, too, that officers are unduly prone even when they are living and eating in their own homes or billets, though I do not know of any figures to support this statement. Like so many dramatic events in epidemiology, the high officer incidence of hepatitis seems on analysis to be due not to a single decisive factor but to a concatenation of circumstances: not only to communal crockery but perhaps to a higher susceptibility of the officer class, a greater opportunity for contact with strangers, the relative youth of flying personnel, and other unrecognized factors. It is a pity that a clue which at first sight seemed so promising has led in the end to no definite conviction.

Even if we accept the hypothesis of infection by eating-utensils it should be noted that it does not imply an excremental spread of infection. Similar precautions have to be taken in anatoria for tuberculosis to prevent the infection of crockery with tubercle bacilli in the sputum. This point is made because of a hypothesis that the disease may be spread by the excreta rather than by droplet infection. It is certainly surprising that in spite of the frequent admission of cases to hospital in the pre-icteric stage, which is often regarded as the most infectious period, several hospitals have had not a single case of cross-infection in the wards or of transmission to hospital staff. But this could be paralleled in pneumonia and cerebrospinal fever, which are certainly air-borne. The place localization and the seasonal incidence may be more suggestive of transmission by excreta, and it has been stated that on taking up position on a clean site there is no jaundice and on a dirty site there is jaundice, though little evidence is advanced for his statement.

It was noted this year in North Africa that jaundice declined sharply after the first December frosts. This is reminiscent of poliomyelitis, in the spread of which flies are now believed to take part. The curve of the fly population figures in North Africa and Egypt has peaks in May and October and a trough in August, when it is too hot for the flies to breed. The curve of the incidence of dysentery, which is largely a fly-borne disease, has the same bimodal outline. The jaundice curve, on the other hand, is monophasic, with a single peak about October and November. This has been used as an argument against transmission by flies, but it is only fair to the hypothesis of transmission by flies to point out that gonococcal ophthalmia in Egypt, which is almost certainly transmitted by flies, has the same monophasic autumnal incidence (Wilson, 1936). It is only in autumn that the temperature and humidity are high enough to allow the gonococcus to survive during transfer, and the same might be true of the virus of infective hepatitis. Finally, it has been noted that jaundice occurs at a time when culicine mosquitoes are prevalent. There is no conclusive evidence that insects or excreta spread infective hepatitis, but here is enough to make experimental work in this connexion desirable, and indeed rather urgent.

### Discussion

Some people are of the opinion that we already have more aets about the epidemiology of infective hepatitis than we an digest and that little more can be learned from field studies until techniques are invented for the detection of the virus or the discovery of latent or subclinical infection. Certainly such techniques would constitute an enormous advance, but it is doubtful whether we do yet possess all the data which could be secured about infective hepatitis as it is now occurring in an epidemic scale. There is still need for intensive study of the incubation period and mode of spread at the actual time and place of the outbreak. Only the man on the spot knows what people are actually doing; whether, for example, men listed as flying personnel are actually flying and, if so, how often, how long, on what types of machine, whether on operations or not, and so on. Again, cases of jaundice in different ranks may actually be occurring in the same place. Other factors, such as movements, replacements, and contacts of troops, incidence of jaundice in the civil population, topographical distribution in units, cook-house hygiene, sanitary discipline, flies, and exposure to cold or to strain, must obviously be studied at the time if information about them is to be accurate. There is also still much to be learned from the analysis of data already collected. We ought to be able to answer the following questions, but I do not think we can.

1. To what extent and for how long is the individual protected against infective hepatitis by a previous attack of infective hepatitis, serum jaundice, or post-arsenical jaundice? Lieut.-Col. H. L. Wallace found that 4% of a series of patients with infective hepatitis have a previous history of jaundice. I have already mentioned that an attack of serum jaundice seems to make people more susceptible to infective hepatitis.

2. To what extent is the herd protected by a previous epidemic of jaundice or by experience of a batch of icterogenic yellow fever vaccine?

3. To what extent is such protection, if any, influenced by replacements and additions to the herd?

4. Does the seasonal incidence vary in different places and countries, and, if so, can it be correlated with temperature, humidity, flies, etc.?

5. Is there a similar seasonal variation in the incidence of post-arsenical jaundice?

But although we may agree that epidemiological study of infective hepatitis in the field is still worth while, we can hardly begin to exercise rational measures of control until we can answer questions like the following: (a) What are the vehicles of infection—nasal secretions, urine, faeces, food, eating-utensils, fomites, etc.? (b) What is the normal route of infection? (c) Can flies, mosquitoes, or other insects transmit the disease? (d) How can the virus be inactivated, with special reference to camp hygiene? (e) How early in its course and how late is the disease infectious? (f) What are the factors which affect susceptibility to infective hepatitis?

These questions cannot be answered without experiment. Laboratory workers will doubtless continue to try to infect animals in the hope that eventually an animal or a strain of jaundice will be found that will take. At the present moment however, no immediate line of advance seems open, except transmission to human volunteers. This is not an encouraging outlook; for knowledge rarely increases rapidly when a disease can only be studied by human experiment, as the history of leprosy, trachoma, and pernicious anaemia shows. In the case of homologous serum jaundice we might well quail at the risks of human experiment; for of the 109 recipients of K. 60 the notorious batch of pooled measles convalescent serum 41 sickened—37 with jaundice—and 8 died (Memorandum by Ministry of Health, 1943). Fortunately this seems to have been a most unusual serum, and where homologous serum jaundice has developed after yellow fever vaccine the mortality has been of the order of 1 per 1,000. We have no reason to believe that when infective jaundice is deliberately induced the mortality will be higher than that of the spontaneous infection; and that again is probably less than 1 per 1,000. Nor need we believe that the incubation period will be longer than the usual 30 days, though Cameron's experiments suggest that it might be. Nevertheless, the number of subjects who may be encouraged to volunteer for experiments on the human transmission of infective hepatitis is clearly limited, particularly in time of total war, and a similar limitation must be placed on the circumstances under which it may be permissible to propagate the infection in the community. I am sorry it is not possible to be more optimistic about the prospects of research on infective hepatitis, and I repeat that the prospect might change overnight if we discovered a suitable animal. But at present it is a hard problem. If it had been easy it would have been solved years ago.

### Conclusion

Much of the information in this article is derived from confidential papers and reports, and from conversations during a recent brief visit to North Africa. It is not an official pronouncement, and I may well have made mistakes in reporting what I have heard and seen. In one matter, however, I think I shall not be contradicted. The volume and the quality of the work of physicians serving with the Forces over-seas are of a very high order, and they are perhaps not sufficiently appreciated by those of us who have remained to practise medicine at home. A military general hospital in the field may admit more than three times as many patients a year as a teaching hospital in Great Britain. This has been a physicians' war so far, and many more men in the Forces have been treated for sickness than for injury. In the first half of the war civilian surgeons in this country treated more casualties from enemy action than their opposite numbers in the Services. On the other hand, physicians at home have had no experience to compare with the epidemics of venereal disease, malaria, and jaundice, and the outbreaks of diphtheria and poliomyelitis, with which their colleagues in the Service have so brilliantly contended.

### Summary

Infective hepatitis is one of the three most important diseases in the Mediterranean theatre of operations and one of the major medical problems of the war.

Orthodox opinion is that the rate of progress in knowledge and technology is expected to be rapid, but useful knowledge is expected to be slow and human progress is expected to be slow.

In the absence of a susceptible animal, progress in knowledge and control of the disease cannot be expected to be rapid, but useful information might be derived from carefully planned human transmission studies.

**EVACUATION AND EVACUATION SURGERY**

the transference of the patient to the base.

at 2 factor which influ

### EVACUATION AND EVACUATION SURGERY

The post-operative transference of the patient to the base, with its strains, vicissitudes, and delays, is a factor which influences treatment to an extent requiring further consideration. Already some idea has been given of a few of the difficulties.

— campaigns the surgeon often had only a very rough idea of the nature of the further evacuation, and consequently

In these campaigns the surgeon often had only a very rough idea, occasionally he had none, of the nature of the further journey of his patient, in terms of time, distance, and conveniences. While he knew that patients would be scrutinized at every halting-point, he appreciated that the less they or their dressings required to be disturbed on the way the better.

Road, rail, air, and sea, all were used. Road evacuation undoubtedly does more harm to patients and their wounds than do the other forms. An ambulance speeding along the wide smooth roads of England gives an impression of comfort and rest that is misleading. The roads in the countries of these campaigns, apart from a few main highways in Italy, do not compare, and by the time an army—or rather two armies—the retreating and the pursuing—have passed over them with the juggernauts of modern war the best become pock-marked and irregularly crumbled at the edges. That is putting the matter at its best. In the desert tracks became furrowed and, when the sand was soft, vehicles floundered like small craft in a choppy sea. In country cultivated but not populous, roads were narrow and unsurfaced. Wide vehicles forced one another into side ditches. As the cookery books say, add a little water.

If he lie inside recumbent on a stretcher it is an education for a surgeon to make an ambulance journey of some 50 miles over rough roads. Because of the swaying and jolting it is a nauseating affair, however careful the driver may be. What, then, of the less fortunate patients? There are some to whom a road journey of a mile or two, even less, would be fatal. To others the risk may be considerable; to none is it beneficial. The appreciation of the value of general rest for injuries comes, therefore, to a young surgeon. He is apt, in a moment of enthusiasm, to say such things in terms of local

Appreciation of the value of a young surgeon. I think, a little slow to calculate overmuch in terms of plaster-of-Paris age, to splint is not necessarily a patient's rest. A limb well splinted naturally also leads to local results by the lowering of resistance to infection. When undertaken as described, when undertaken by patients, there may be given

What happened to patients and their wounds on and after such road journeys as have been described, when undertaken a day or two after operation? Some examples may be given.

In cases of compound fracture due to road accidents in civilian experience as forward consulting surgeon, M.E.F., 1943, and January, 1943, to

practice limbs are frequently put, after operation, in skin-tight  
plasters and the patient is retained in hospital. Splitting of the  
cast is often done as a routine for safety, and certainly is fairly  
often required. If similar patients in these campaigns were  
sent on a road journey of several days' duration, not only was  
it found that splitting of all such castings was essential, but  
that splitting was not enough and that a split padded plaster  
was required. Otherwise circulatory risks and disasters occurred.  
In abdominal cases the journey, if undertaken much before the  
tenth day, frequently produced an intractable ileus. Patients  
with chest wounds who were still showing some dyspnoea or  
cyanosis while at rest became acutely embarrassed. Shocked  
patients had their shock increased. Patients with early infection  
had their resistance undermined.

Thus the clinical needs clashed with the administrative necessities. Theoretically there could be a multitude of holding units close to the line. That is the ideal of the medical service. In actuality, however, the medical units were few and far between. They were not to be fought with hospitals instead of tanks, or with

Thus the chain of command was maintained. Theoretically there could be no compromise. That is the ideal of the medical units close to the line. That is the ideal of the services. But wars are not to be fought with hospitals instead of artillery dumps, with ambulances instead of tanks, or with savings instead of rifles. Compromise, then, was required. The serious cases had to be held. Half alive in the field is better than dead at the base. The proportion of casualties detained where they were operated upon varied between 3 and 5. All else had to start down the chain. The chain itself had to be reasonably clear. Along it occurred what might be called evacuation surgery. This, in spite of the term "coffee-milling," was a skilled business and had never to have a casual air about it. Vigilance and ability were required to deteriorate and retain and treat those whose condition had deteriorated on the way, to note any overlightness of plaster casings, to renew, when necessary, dressings and casings, to spot and treat secondary haemorrhages, and to be helpful in the many little but important ways that made for the patients' comfort on their further travels.

### Air Evacuation

**Air Evacuation**

Air evacuation prevents attractive possibilities and has often provided a magic carpet to transfer patients to a base expeditiously in a few hours, on a journey that would otherwise necessitate days, even weeks. Many thousands of sick and wounded in these campaigns were so transferred.

On rare occasions when the plane brings wounded patients home, and dealing only with post-operative patients, the air evacuation has been a

Onmuting rare occasions when the plane brings wounded or injured men to the surgeon, and dealing only with post-operative transfers, it must be observed that air evacuation has limitations that are not apparent at first sight. To the popular imagination the idea of the seriously wounded being operated upon quickly, and immediately transferred to the base by air, is a fascinating one. But these seriously ill patients, operated upon well forward, would necessarily have to make a road journey to an aerodrome and another road transport to explain end. Enough has been said about road transport. Occasionally in why such journeys should be avoided. Occasionally in the desert a landing strip could be made alongside a casualty clearing station. In closer country that ideal will not be possible until planes can land with the uncertainty of the planes. Except was another drawback—the uncertainty of the planes. Except for a few special ambulance planes in the desert, casualties were always removed in freight planes which brought up fighting stores and were fitted with stretcher racks for the return journey. There was, due to war exigencies, always some uncertainty as to what planes might be coming and whither they would be returning. While this was a difficulty that was got over in part by special sections of field ambulances sited on the aerodrome, the latter was no place to keep the serious casualties hanging around. The saying that no one is fit for the air who is not fit for the road became more than a saying, it became a rule.

The highest values of post-operative air evacuation were two. The first was to transfer certain patients who, though fit for road evacuation, were liable to special dangers if the journey were protracted. For example, a patient with a fractured femur might, without air evacuation, be some weeks in a Tobruk plaster. In this the limb is not so much "set" as made comfortable for transport. Any malposition might therefore be well organized before more adequate traction methods could be applied. A second example is that of a patient with a penetrating brain wound, where the routine daily treatment

\* Based upon experience as forward consulting surgeon, M.E.F. and A.F.H.Q., in October-November, 1943, and January, 1943, to February, 1944.

and observation to avoid and detect the onset of meningitis or brain abscess are of prime importance. The second high-value of air transfer was the less spectacular one—the removal of large numbers of both sick and wounded from the front areas. Such air removal lessened road congestion, it saved petrol, it avoided using up medical stores and food and the so many other things that had to be brought up, and it lessened the work for nurses and orderlies, who were now freed to give the retained patients more attention.

Air evacuation undoubtedly will prove in time a still more powerful aid. In these campaigns it had necessarily always something of an *ad hoc* air about it. But war calls for such arrangements. *Ad hoc* meant very often *ad astra*.

Rail and sea evacuation need little consideration. Their advantages over road transport are obvious. The retreating enemy never failed to blow up any railway bridge. There was always, therefore, a delay before the line was ready and a railhead established. Once that had been done, both administrator and surgeon were considerably relieved.

### THE FIELD SURGEON

With the intermittency of the fighting the field surgeon's professional life alternated between idleness and activity, between boredom and gusto, between rest and exertion. The quiet periods, when of any duration, were far the most trying. Probably it is less irksome to have no patients than to have very few. Not always are there many casualties; not everyone can be in the forefront at the same time. Efforts were continuously being made to give all their share of each level of work. Those at the back, it should be noted, were always at the service of the local population, now returning pathetically after the tide of battle had passed. The mines which bestrewed their land found many victims. The attractive highly coloured little booby-traps, simulating fountain pens, shaving sticks, and the like, were eagerly picked up by children.

The surgeon had, of course, a regimental life as well. He and his team had to be adroit at quick setting up and taking down of their gear, at neat and economical lorry-loading, at tent-pitching and tent-striking, at finding the next site by a map reference without mistake or delay. The surgeon had his stocks to watch and maintain. He had to look after and train his orderlies. The labours of the latter do not finish with the operation, and it is fair to say that to them their work is more exacting than is the surgery to the surgeon.

It has been said, and often repeated, that war surgery is the worst possible training for the young surgeon. What, of course, is meant is that it is the worst possible training for civil surgery. The view is, I think, both unfair and thoughtless. It disparages, in its narrow outlook, a type of surgery devoted to the care and preservation of the flower of the nation's manhood, a manhood which has shown itself no less resolute than its forebears. Military surgery, from a broad viewpoint, ranks as high a form of surgery as any, and considerably higher than much of the "officially keeping alive" of the aged or already doomed. In the early days of the war many young men sacrificed much, in career and prospects, to help their fellow men. Let it not be forgotten.

War wounds and field conditions certainly provide work of a rougher nature than is to be met with in times of peace. But field surgery has educational and other values that are not to be despised. There is development of clinical and operative judgment in many directions and of quick decision and self-reliance in times of crisis. There is, because of the frequent daily need for personal supervision, an invaluable education in post-operative treatment. There are resuscitation and transfusion, and all their details, to be performed on a huge scale. There is an appreciation of infections that would take long to acquire in civil life. There is the necessity for clear and concise note-making so that a patient's wounds and treatment can be readily appreciated on his further journeys.

The drawbacks are those of relatively coarse manipulations and of an association with a lower standard of asepsis that may dull the surgeon's sensibilities. In rush periods the stench of stale blood and the reek of primus stoves, the continued sight of blood- and mud-stained clothing and dressings and of his own streaked apron, the depression perhaps of the

necessity for several amputations, all these may well at times make a weary surgeon wistfully recall other theatres he has known and doubt if it is surgery he is practising. But such periods fortunately are infrequent and do not last long. In the quieter intervals he can achieve an orderliness and a cleanliness of very high standard. Provided, therefore, that the young surgeon is not kept overlong in the field, the drawbacks may be discounted. It was the rule in these campaigns not to allow him to remain in the field longer than 12 months. Thereafter he returned to a base hospital, invariably against his will. But it was thought best for his own future that it should be so, and the change over allowed of a greater number being trained in forward work.

The necessary proper introduction of strangers to field surgery cannot, alas, always be provided. The exigencies of war do not always permit of it. That proper introduction, however, was achieved in the Italian campaign, when no newcomer to the field treated fresh casualties without having had an apprenticeship comprising periods at a base-hospital in the fighting zone and at a staging post on the lines of communication. Without these experiences, with their wealth of demonstrations of the effects of travel upon the recently operated and their wounds, he was likely to make many initial mistakes.

What are as much wanted of a surgeon in the field as skill are character, physical fitness, and adaptability. There are required a zest and a capacity to go on doing a good job for many consecutive hours, perhaps for several consecutive days, to be up and about at all hours, to take the rough with the smooth, to think in terms not only of technique but of humanity, to perform the little kindnesses as well as the big operations.

Of the need for adaptability little may be said. The different tents and buildings, the need for modifications of apparatus far from an instrument shop, the improvisations necessary to meet this or that emergency, all these difficulties had to be surmounted by the surgeon's ingenuity, aided by the ever-helpful engineer workshops.

Of character and adaptability and skill it may be said there was abundance in the surgeons in these campaigns. What some lacked in experience was readily made good by character and application. Their work was marked by high endeavour and a sense of pride. Thomas Atkins ahead was doing a fine job; the surgeon behind would not suffer in comparison. The rigours of the field further expanded and developed native character and adaptability. Who shall gainsay that these are not unworthy attributes of a surgeon?

### SOME TRENDS IN TREATMENT

Excellent articles have already been written by some of the field surgeons, general and special, and more will doubtless appear. Such are to be hoped for, as only by multiple presentations will a comprehensive picture be obtained. Some notable differences in practice and results will be observed in these papers. They should not be taken as necessarily implying different abilities or even always different opinions. Much depended upon the period in the campaigns, at what level the surgeon was working, the presence or absence of special teams, the pressure of casualties, and the distance from base hospitals. Individual statistics are thus apt to be misleading. Some of the best surgeons had long forward periods among the most unpromising material, and may be tempted to remain mute.

Accordingly much is to be hoped for from the continued insistence that routine field reports would furnish details of all deaths and of interesting cases, including all abdominal ones. (The records of specialized teams were more easily kept.) The number and name of the casualty had always to be included. The follow-up of these should provide wonderful statistical material after the war, in combination with the similar but more comprehensive record demanded of surgeon at base hospitals, entailing like notes on all abdominal, chest joint, and vascular cases.

Here I propose to limit myself to brief consideration of some of the trends of treatment, and to a very few personal observations. In some branches, such as the neurosurgical and maxillo-facial specialties, changes have been more towards quicker

contiguity with the casualty than in technical procedures, permitting the latter to be more often ideally performed. Exploitation of the sulphonamide series and penicillin has, of course, in these specialties as in others, provided scope for comparison.

"We learn from history that we do not learn from history." Some lessons, it must be admitted, have had to be relearned. Every war and every campaign in every war provide differences from the last. It would be foolish to teach surgeons strictly on the lessons of these campaigns. But great principles are common to all; it is the details which change, and details in the field approach principles in importance.

While the transfusion service operated under the directorate of pathology, it is only right to precede any surgical considerations with a tribute to its magnificent organization and achievement, just as its aid to the patient precedes that of the surgeon. Resuscitation naturally plays a considerable part in field surgery. The transfusion element of this was developed in these campaigns to an extent never previously attempted or achieved. While at first sight it would seem likely that, to an army often so far from its base, plasma and serum would have been more forthcoming than blood, in the event there occurred the paradox of whole blood being employed in greater proportion to plasma or serum than some other authorities think advisable or necessary.

The difference is one that must be left to be thrashed out between transfusionists and between surgeons with wide experience of both methods. It is difficult for those brought up, so to speak, on whole blood, to argue. What the surgeons saw was good and they sought no change.

The early initial view that transfusion was perhaps a little overdone came to be modified. There was a fear that surgeons were perhaps delaying overlong, waiting for transfusion to bring about always the same high degree of improvement. With time, however, the transfusion officer was quickly ready to speak when he felt that further transfusion was unlikely to be beneficial. The transfusion officers developed a fine clinical instinct. All statistical comparisons between this and the last war will be misleading if the influence of the more highly developed transfusion services is not taken into account.

### General Wound Treatment

It had been realized long before these campaigns that treatises on war surgery written just before or during the early part of this war had placed over-emphasis and displayed over-optimism on the possibilities of wound closure after excision. Much of the argument was based upon civil and last-war experience in France. Conditions in the latter were mostly static, the wounded were promptly received, and lines of communication were short. More important still, the patients were usually retained if so treated—a point hardly clearly enough pointed out. It is one thing to excise and suture a wound if the patient is retained under scrutiny; it is a very different matter so to do and send the patient immediately on a journey of several stages.

Immediate suture after excision had no place in these campaigns. (I except head and abdominal wounds and the rare favourable opportunity in an outlying unit which could retain patients until the stitches were due for removal.) The time lag, which averaged well over 12 hours, was too long and the necessity for early further transmission was too great. Occasionally a large flap wound was obviously the better to be tacked at a point or two; but that did not entail closure, and the fact that such stitches were in position was made prominent on the field medical card. Attempts at closure in earlier campaigns, and by new-comers later, met with disaster. What were unfortunately largely precluded by the long lines of evacuation were delayed primary and early secondary suture, procedures always to be borne in mind as time-saving where the retaining base is only a few days distant. The advanced base hospitals were always too strained to permit much of this. In the desert, because of the long time lag and because of the absence of severe infections, excision of wounds became modified in degree. More emphasis was required on decompression of the wound, the laying open and freeing of tension, rather than on the removal of much possibly

soiled tissue. Damage in the deeper layers is usually much more extensive than to the surface. In Sicily, and especially in Italy, however, a more radical excision was required to guard against severe infections, particularly gas gangrene, which occurs largely in direct ratio to two factors—the time lag and the thoroughness of the initial treatment.

The practice of excision of skin dies hard. There seems to be a fascination in removing skin that is entirely unjustified pathologically if the wound is not to be sutured. Skin is very resistant to infection, and superficial cellulitis rarely develops in a wound which has been thoroughly opened up. Dead skin is rightly removed; all else is best retained for a possible late primary or secondary suture, when edges have to be pared anyhow.

There are over-tendencies in some quarters to minimize the value of x rays in forward areas and to frown upon anything more than a rapid look for foreign bodies. Certainly these procedures add to the burden in times of pressure. But repeated travel up and down the line convinced me that these are dangerous attitudes. Many of the most serious complications of infection, particularly secondary haemorrhage, can be traced to retained foreign bodies and the contaminated clothing around them.

Not myself a surgeon in the last war, I am content to believe competent observers who assert that the general appearance and condition of patients in the immediate few weeks after wounding contrast favourably nowadays as against 26 years ago. This they attribute in large measure to the oral sulphonamide therapy which is instituted at once and carried on as a routine throughout travel to the base. In these campaigns movements were at a pace which prevented reliable large-scale observations on the effects of administration of this type of drug by local and other routes. But the drugs were given. While it may be hoped from a scientific viewpoint, that opportunities for such research will occur, who would not rather wish that all future campaigns will be as swift-moving? No new therapy, however, has altered in any degree the fundamental necessity for adequate initial surgery.

### Burns

The proportion of burned to wounded was at one time as high as 1 to 10. It may no longer be so high, but it will always be considerable in modern warfare. Tanning procedures in the field had, before these campaigns, proved to be unsatisfactory and dangerous. It was a pity, since painful and time-consuming dressings might have been dispensed with. But the difficulty of asepsis in the field and the strain of the subsequent journey combined to produce a lamentable infection under the tan. Sulphanilamide-vaselined-gauze dressings had taken their place, and still seem the best. Their messiness and their frequent need for reapplication call aloud for something better.

A personal impression has persisted that in the treatment of burns perhaps too much emphasis has been put on the danger of infection. Not that these are not great. But there has been a tendency to be over-impulsive in the early cleansing of severe burns. The patient is admitted, given plasma to restore his pressure to some 90–100 mm. Hg. and is then anaesthetized and cleansed. This cleansing proves almost always more lengthy than is anticipated, and its effects, combined with those of the anaesthetic, are not infrequently followed by a quick morbid result. While the plasma had done much, the patient was still not enough on the right side of life as to be easily pulled back. A policy of withholding anaesthesia, retaining the patient, and doing his extensive dressings in stages under morphine over a period of even three or four days seemed in these severe cases worth trying, and it was my impression that some striking recoveries were obtained.

Due care was taken of the other general considerations in burns, such as plasma administration and control. It may not be out of place here to record that "plasma for burns" has tended to become a slogan, inducing forgetfulness that whole blood may be needed at a later stage.

### Immobilization

The supremacy of plaster-of-Paris casings over other forms of splintage was clearly demonstrated on the testing lines of

communication. There was, of course, no doubt of the issue, but the contrast could be well observed where for reasons of quick access and scrutiny a limb had been splinted otherwise for the journey. (Generally such quick access can be obtained with adaptations of plaster technique.) The necessity for both padding and splitting the cast has already been noted: limb casts for compound fractures between front and base are primarily for comfort; the position of the fracture, within reason, is a secondary matter.

The Tobruk plaster, evolved for the fractured-femur patient (spicas had been discarded) but suitable for other lower-limb injuries, underwent several changes. It started off as a modification of a method used in the last war, in which the bent Thomas splint, with the fixed extended leg within it, had two cuffs of plaster round both it and limb. The first "Tobruk" was an encirclement of the whole length of the splint-and-strapping-extended limb with plaster, adequate padding intervening between limb and casing. The next type incorporated a supporting posterior slab as well. A further development was first to apply a split padded plaster cast to the limb, including the foot, bringing out the extension tapes through holes in the casing, then applying the Thomas splint with cuffs of plaster round splint and cast at thigh and midleg level. There is probably little to choose between the types; all can be done well or badly. My own preference is for the first type, provided plenty of padding is inserted. There is certainly a difficulty with it of preventing some outward rotation of the limb below the fracture; control with the independent foot-piece is more difficult to achieve. But it can be done. A valuable feature of this type over the last described is that it takes half the time and consumes half the bandages. But it was also more favoured, as more comfortable, at the receiving end of the line.

If, as a refinement, the plaster bandages be applied very loosely round splint and well-padded limb, and fingers be kept running up and down the side bars of the Thomas splint, then the centre part of the cast forms a roughly circular tunnel for the limb.

While the "Tobruk" was a satisfactory method, none of the various types of immobilization for compound humeral lesions proved quite as efficient. Thoraco-brachial casings were applied with various little modifications. In general this patient was not as comfortable during transportation as was the fractured-femur patient. Were he fit enough to sit up on the journey then he rarely had any complaint.

The thoraco-brachial plaster is to be thought of for more than a fractured humerus. Shoulder-girdle conditions, such as a compound fracture of the clavicle, need similar support on a long journey.

#### Wounds of Joints

The practice of closure of joints after cleansing (omitting skin closure) where enough tissue is available has followed that of the last war. What was as important, and what was aimed at although not always practicable, was the retention of such patients in the field. They were of a type which generally could reach a casualty clearing station, and it was important they should, because their detention under the supervision of the surgeon who performed the excision was most desirable and was at this level more practicable. However adequate was the plaster immobilization it could never be as absolute in transit as in total rest. Nor was the surgeon at staging posts so informed as the original operator, however good the notes. But, naturally, where there was pressure from in front, these patients could not be regarded as being in the same class of urgency for detention as some others.

#### Amputations

The practice of saving all that was possible where amputation was required was well worked out before these campaigns. No elaboration is required here, since the merit is obvious. It is to be hoped that any suggested methods tried out at general hospitals, whereby primary or near primary closure at sites of election seem assured by small changes of technique, will be tried very cautiously in the field. The standard of asepsis and the rigours of the journey are likely, in this as in many other ways, to upset post-operative healing.

The approximation of flaps without tension by no more than three or four stitches tied over a thin roll of sulph-anilamide-vaselined or dry gauze became general practice. Guillotine amputations were regarded with ill favour, but rapid disarticulation through the knee-joint, as a less shock-producing measure than thigh amputation, was resorted to on occasion with a probably increased chance of survival in critical cases.

The exception to conservation is the compound fracture of the tarsus. Experience showed that practically all of these required a foot amputation sooner or later. It was therefore better in my opinion to do this at once, save in the mildest cases. The immediate performance ruled out a long period of ill-health from osteomyelitis and eliminated the mental woes of patients over whom hung the inevitable loss.

#### Chests

There had been, before el Alamein, a distinct swing over from the radical practices in this specialty advocated in the last war. A much more conservative attitude had been established—perhaps ultra-conservative, since it suggested that, apart from cases in which pressure symptoms were present, aspiration of a haemothorax was better delayed until the patient reached the base, even if that took as long as seven days. With routine sulphonamide therapy the risk of infection was deemed likely to be less than if repeated aspiration were carried out in the field.

This policy was soon dropped. Most patients with a haemothorax reached a casualty clearing station for their surgical treatment, and it became one of the chief interests of its medical specialist to share in their after-treatment and to perform aspiration routinely, starting usually some 48 hours after the time of wounding. The practice of air replacement, which had also been advocated, was discarded as unnecessary from the viewpoint of possible recurrent haemorrhage and as somewhat likely, if infection were present, to favour a total empyema. Generally speaking, chest cases were fit to be evacuated to the chest centre before the onset of a degree of infection requiring drainage.

While, by and large, conservative measures were in the circumstances undoubtedly right, they may be carried too far by forward surgeons and insufficient débridement performed, particularly as regards clearing of broken rib spicules which may introduce infection. With an experienced chest team close behind him, and with often much more work on his hands, the field surgeon, unless he had special training and interest, was, however, probably erring on the safe side.

One real danger to be noted in these patients was the circulatory embarrassment resulting from overmuch transfusion. Transfusion officers were soon aware of this, and did not give more than was sufficient to raise the blood pressure to some 90-100 mm. Hg.

#### Abdominal Wounds

By the time of el Alamein standardization in traumatic abdominal surgery was taking shape. What remained was its more general adoption both in operative technique and in the equally important after-treatment. It was still to be realized by some that the time lag since wounding was not as important a factor as had been held out. Not only time but the nature of the lesion is to be considered. One man may have several large apertures in his bowel and be bleeding appreciably; another may have only a tiny perforation and have bled little. The idea that it was of no avail to operate after 12 hours was still rather prevalent. Patients with colonic tears have been successfully dealt with even after 48 hours. In the desert particularly, the large-bowel content was frequently solid and pollution of the peritoneal cavity relatively slow.

In one invasion where surgeons received casualties within an hour or two of wounding there was an impression that such patients had not done as well as previously when there had been a greater time lag. This is in keeping with last-war experience, that one can be too hasty in operative approach to the abdominally wounded.

Among the operative measures routine exteriorization of colonic wounds, whether intra- or retro-peritoneal, was probably the greatest change from last-war practice. The results of resections of bowel confirmed previous opinion of the hazards

of this sometimes necessary proceeding. The almost routine institution of continuous post-operative gastric suction undoubtedly time and again saved lives by averting the ileus which so commonly occurs whether bowel be injured or not. It matters little how many layers of stitches are inserted to close a bowel aperture if distension is allowed to occur; one layer of Lambert stitching suffices if the bowel wall be kept flat. The restoration of lost fluid by intravenous administration of a sufficient quantity kept pace with the withdrawal.

There was early realization that abdominal patients had to be worked for and fought for, and that even in some of the apparently unfavourable cases a good result can be got with such care. By the excellence of the transfusion services and by the greater exploitation of forward teams probably many more desperate cases reached an operating table than did in the last war. These two factors will invalidate any real statistical comparison. These desperate cases included not only patients with abdominal wounds but also those with both abdominal and other severe injuries such as compound fractures of the long bones. The combination is not uncommon, and is fought with more than fourfold risks.

With the above practices thoroughly carried out, with routine four-hourly post-operative morphine, and with the retention of the patient for ten days where he was operated upon, it is likely that the end-results did not at least fall lower, despite the more desperate cases, than in past wars.

In order to make this paper comprehensive and yet bring it into the limits of an article I have had to omit much. Particularly do I regret omitting the names of individuals. To have mentioned some and not all would have been contrary to the spirit of the Eighth Army, in which brotherhood, kindness, and helpfulness abounded.

Acknowledgments to my seniors I make with gratitude. To Major-General W. H. Ogilvie and Brigadier J. Weddell, the chief consulting surgeons of M.E.F. and A.F.H.Q. respectively, I owe much for opportunity, advice, and support.

Consulting surgeons cannot, however, exercise their full abilities without the sympathetic co-operation at their administrative heads. The successive D.D.M.S. of the Eighth Army during this period, Brigadiers J. Walker, C.B.E., M.C. and E. Phillips, C.B.E. D.S.O. M.C.—were both out to be helpful in any and every way, and the more longer association with the latter, many of the principles of organization described above were worked out. In advanced battle areas and on the west side of Italy there was the same teamwork liaison with another D.D.M.S., Brigadier R. W. Gallowsay, C.B.E. D.S.O.

A good general values his medical services. In his appreciation of their administrative needs and difficulties and in his ready sympathy for the wounded, as displayed by numerous visits to medical units in the field, General Montgomery showed himself no less lacking in humanity than in strategical genius.

## SOME DANGERS OF SULPHONAMIDES IN EAR INFECTIONS

BY

A. R. DINGLEY, F.R.C.S.

Surgeon, Royal National Ear, Nose and Throat Hospital

The use of the sulphonamide drugs in otitic infections is not without its dangers, and it appears to be insufficiently realized that their administration at the wrong time or in inadequate dosage may so mask symptoms, distort the clinical picture, or interfere with the acquisition of immunity that the patient's life may be jeopardized as a result. A distinguished otologist of conservative surgical outlook recently said that he was now opening more mastoids than in pre-sulphonamide days, and this he attributed solely to the increased incidence of these atypical and sulphonamide-distorted types. It is not going too far to state that some otologists are swinging round to the view that these drugs may be so dangerous as to be contraindicated in the treatment of otitic infections unless certain criteria are observed and followed. Too often has sulphonamide been used as a substitute for surgical drainage: too often has it been given in ignorance of the nature of the micro-organism present; too often has its use been applied at a stage of the infection when its administration could only mislead and confuse.

Acute suppurative otitis media usually begins with intense earache, fever, and deafness, and on examination the drum-head is bulging, pulsating, and usually of a purple colour. Such a picture calls for immediate myringotomy, and no amount of

sulphonamide can ever take the place of this necessary step. After drainage is established and the micro-organism isolated, treatment with the most appropriate sulphonamide may be instituted, particularly if the fever persists, and its use may hurry on the resolution of the infection.

Again, after two or three weeks of otorrhoea have passed and subsidence of discharge or fever has not been achieved, the danger of continuing sulphonamides as a substitute for mastoid drainage is a very real one. At this stage of the infection the problem is likely to become one of early osteitis with decalcification of bony trabeculae, destruction of mucoperiosteal cell lining, and thrombosis of vessels in the mastoid cavity. Quite apart from the fact that sulphonamides will not reach the local area owing to inadequate blood supply in the breaking-down tissues, it is unwise, by introducing the masking effect of sulphonamide, to deprive oneself of the presence of signs and symptoms which would indicate the need for surgical drainage.

### Three Illustrative Cases

The following three cases may help to illustrate some of the dangers which may be encountered:

**Case 1.**—A boy aged 10 had an attack of earache at his preparatory school; this was treated with sulphonamides, apparently got better, and the aural condition was subsequently disregarded. His general health remained unsatisfactory and he lost weight—signs which should have been given greater consideration. On arriving home for the holidays one month later the parents were alarmed at his appearance, and noticed that he complained of vague headaches. He suddenly became ill with signs of meningitis. A pneumococcus (Type 1) was isolated, and after four or five days an otologist was asked to see the boy in order to exclude possible "ear trouble" which, however, was not suspected by the medical attendant. The membrane was congested, but no other sign of abnormality was noted. It was felt certain that the mastoid was involved, and this was proved to be the case, both by x-ray and at the operation, which unfortunately was too late to save the boy's life.

**Case 2.**—A doctor aged 43 was taken ill with severe earache, fever, and some deafness; these indications should have suggested immediate myringotomy, but he dosed himself erratically with tablets of sulphapyridine instead. There was an improvement in the symptoms, and until the next bout of pain nothing much was thought of the matter; further tablets of sulphapyridine were sufficient to quiet the condition down so as to make it bearable, but on the fourth morning the pain became intense, and was accompanied by severe headache. The membrane was bulging, and the middle ear obviously contained pus. By this time the meninges were involved, and paralysis and loss of sensation in the contralateral face, arm, and leg manifested themselves. After a most stormy three weeks with turbid C.S.F. (Type 3 pneumococcus), periods of coma, and incontinence, recovery eventually took place after large doses of sulphonamide, Type 3 pneumococcus serum, and penicillin; but the recovery was, to say the least of it, unexpected. A subdural abscess over the greater part of the right hemisphere was found; this was rendered sterile and was absorbed as a result of penicillin treatment. In this case an early myringotomy would in all probability have cured the infection without complication.

**Case 3.**—A call was received to visit a boy aged 10 with a mastoiditis. On inquiry as to the length of history, the curious answer was received that the duration of the ear involvement was four days; this appeared to exclude the possibility of surgical mastoiditis altogether, and the diagnosis was assumed to be incorrect. On examination, however, the mastoid process was swollen and extremely tender to the touch; the ear-drum was oedematous and bulging, and the boy deaf. Realizing that such a condition could not possibly have come about in four days, inquiry was made as to any previous earache, and this resulted in the admission that five weeks earlier there had been an attack of earache on the same side, which was treated with a sulphonamide, had "cleared up," and had since been quite forgotten. It is obvious that a silent necrosis had been taking place in the mastoid process all this time, and that owing to the influence of the sulphonamide the drum had not perforated. The usual signs and symptoms were masked, and it was fortunate that the ultimate state of the ear was easily treated by surgical drainage, and that, unlike Case 1, an invasion of the meninges or the lateral sinus did not present itself as evidence that the ear was still involved. (Infection was with a haemolytic streptococcus.)

### Some Points for Guidance

To summarize, it would seem pertinent to draw up a few points for guidance in treatment of otitic infections by sulphonamides.

1. Sulphonamides will never take the place of necessary surgical drainage, and should not be expected to do so.

2. Treatment of acute suppurative otitis media by a sulphonamide should be reserved for the period after incision of the membrane and bacteriological investigation. If the fever is maintained, the appropriate sulphonamide may be used in full dosage (day and night), but not after the end of the second week.

3. After two, three, or four weeks the condition of the ear, if still actively suppurating, is again becoming one that potentially requires surgical drainage, this time of the mastoid; and signs and symptoms justifying intervention must not be masked by the administration of sulphonamides, which at best will rarely reach the local area but will distort the clinical picture as a whole.

4. Wholesale use of sulphonamides in otitic infections is to be deprecated.

5. If a sulphonamide has been given before drainage, the most valuable help in assessing the beneficial effect of the drug is gained by examining the drum-head frequently. If this continues to bulge myringotomy should not be delayed, because the condition, which otherwise appears to be improving, is in reality becoming more perilous. Persistence of deafness is also a strong indication that all is not well.

6. Patients taking sulphonamide drugs sometimes do not acquire any resistance of their own to the infection with which they are contending, and it would seem that recurrences are more likely in these cases, which, in addition to developing no immunity to the infection, may find the micro-organism has become sulphonamide-resistant. Recently a schoolboy had five extremely severe and prolonged attacks of tonsillitis (haemolytic streptococci) over a period of three and a half months; each attack lasted at least a fortnight, with high fever. All attacks, except the last, were treated with sulphonamides, and it was assumed that, in addition to developing no individual immunity, the micro-organism had become sulphonamide-resistant. Tonsillectomy was uneventful, and has resulted in freedom from any further trouble.

7. It is needless to emphasize the uselessness and danger of giving inadequate or erratic dosage of sulphonamides. If given at all, full doses at four-hourly intervals, day and night, are required for the full period, and the drug should be continued for a time after complete subsidence of fever.

#### General Comment

It would seem, then, that the chief dangers to be met with in cases of otitis treated with sulphonamides are found in those in which this has been the sole treatment. Such cases appear to the unwary to have been completely relieved, and no further anxiety is felt about the ear condition—and there may be much to support such an attitude. Sometimes the middle ear may return to normal, with recovery of hearing; more often the tympanic membrane, still intact, will remain oedematous, the middle ear congested, and with much loss of hearing. Mastoid tenderness is frequently absent. In such a case it is difficult to know what has been happening in the three or four weeks following the initial infection and apparent subsidence, but such signs and symptoms as pallor, loss of weight, dirty tongue, vague headaches, and (probably most important of all) congestion of the unperforated drum-head, with deafness, should give rise to the suspicion that a slow, latent, and insidious infective process which will not undergo resolution is going on all the time. Such masking is the origin of greater potential dangers than those seen in pre-sulphonamide days, in which the course of the infective process could be clearly followed.

Some help can be gained by radiography, and this should always be used in doubtful cases. Mastoid tenderness and swelling in these atypical cases usually manifest themselves late, about the fifth or sixth week, but not before a critical latent phase has passed, in which the lateral sinus, the meninges, or the brain might just as easily have provided the first sites for an extension of the original infection.

In cases, or suspected cases, of thrombophlebitis of the lateral sinus and brain abscess, reliance should not be placed on sulphonamide drugs, which (a) will fail to eliminate the infection and so lead to catastrophe, and (b) will mask the indications which would suggest the necessity for surgical intervention.

One must remember that sulphonamides bring about a condition of bacteriostasis; unless the patient's immunity is sufficiently raised, either artificially by appropriate serum or naturally by his own efforts, the micro-organism will be capable of regaining its activity. This was well seen in Case 2, in which large doses of sulphadiazine (60 g. in 8 days) brought about such a great improvement that the hemiparesis and hemianaesthesia were almost eliminated and the signs of meningitis had practically cleared; within a few hours of stopping the

drug, however, the patient relapsed into coma, with turbid C.S.F. and incontinence, and was only restored to consciousness with the greatest difficulty by means of intravenous sulphapyridine. Large doses of intravenous serum and penicillin intrathecally and intramuscularly led to eventual recovery. I would appear possible that, in the future, it will be proved that penicillin is capable of bringing about sterilization and absorption of purulent foci, and so dispense with the need for surgical drainage in these cases; this is a feat which it is beyond the power of sulphonamides to achieve.

## BONE-MARROW TRANSFUSION IN INFANTS AND CHILDREN

### INTRODUCING A SPECIALLY DESIGNED NEEDLE

BY

JANET D. GIMSON, M.B., B.S., D.C.H.

Resident Assistant Physician, the Hospital for Sick Children,  
Great Ormond Street

Some skill and experience are required to insert a needle or cannula by the cut-down technique into a vein of the ankle, cubital fossa, wrist, or scalp of premature and small infants. These, however, are a group of patients who not infrequently need parenteral fluid. An attempt has therefore been made to develop a more simple method than the intravenous, and one which would be at least as safe and sure. The bone marrow of the tibia was the site elected. The marrow cavity in the sternum of infants, and in fact of considerably older children, is not large enough for this to be a practicable place for the reception of transfusion agents. Hamilton Bailey (1944) has reviewed the present position with regard to bone marrow for this purpose, and is favourably impressed. He mentions the winged Witts sternal-puncture needle as admirable for cannulization of the sternum in adults. In my opinion, however, a Witts needle or a Tocantins needle leaves much to be desired in use for an infant.

ALLEN & HANBURY'S LONDON

FIG. 1

ALLEN & HANBURY'S LONDON

FIG. 2

The needle illustrated (Figs. 1 and 2) was designed for transfusions into the tibial marrow of infants and children. The following features may be noted:

- (a) The needle is light.
- (b) The distance between the mount and the flange is short.
- (c) The flange is immovable, and so the extra weight of a screw mechanism is avoided. The least possible movement of the needle in the cortical bone is thus allowed and this junction remains firm.
- (d) Four different lengths of needle below the flange have been made: 1/4 in., 3/8 in., 1/2 in., and 5/8 in. Size 18 s.w.g. is suggested for the two smaller; size 16 or 17 s.w.g. for the larger. The 1/4-in. size is suitable for premature infants and neonates, the 1/2-in. and 5/8-in. for about 5-year-old children or over. But the length of needle used should be according to the size of the child and the amount of subcutaneous fat.
- (e) Each needle has its own stylet.
- (f) There is one handle for the set, which can be screwed on to the stylet in order to get a good grip during insertion of the needle.
- (g) The right-angled adaptor, with the strut to keep it firmly in position, leads the tubing along parallel to the limb. The rubber strip attached to the base of the strut is strapped round the limb. Occasionally, owing to fat or oedema or some other irregularity of contour, the strut on the adaptor seems too long and will not sit on the leg and in the needle satisfactorily. An adaptor without a strut is therefore supplied in each set. The tubing should be fixed in two places with strapping—to the limb and to the splint. The splint should extend 4 in. to 6 in. beyond the foot.

### Technique of Insertion

The place chosen on the tibia is the flat subcutaneous plate of bone inferior and medial to the anterior tibial tuberosity. This area is well below the epiphyseal line, above the nutrient artery, and there are no important anatomical structures to which damage might be done between the skin and bone. It will be remembered that a cross-section of the tibia is roughly triangular. A non-touch technique is maintained so far as is possible, as during any operation involving bone.

1. The limb is splinted in a semi-externally rotated position (as for cutting down on to the internal saphenous vein at the ankle).
  2. The skin is cleaned. Local anaesthesia of the skin, subcutaneous tissue, and periosteum is given with 1% novocain. The area is massaged to disperse the anaesthetic, and the anterior and medial borders of the tibia are palpated.
  3. The needle and stylet, with the handle attached, are taken and with the needle at right angles to the plate of bone—i.e., pointing postero-laterally with reference to the leg itself—are inserted with a firm twisting motion as when using a bradawl. The needle passes through the cortical bone with a crisp crunch. The flange rests lightly on the skin.
  4. When the stylet is withdrawn a small amount of marrow may well up or be sucked up into a syringe; it seldom flows out freely.
  5. The adaptor, filled with the transfusion fluid and attached to the tubing from the dripper and bottle (which has already had air bubbles excluded), is fitted to the needle and the flow started.
- Fig. 3 shows the arrangement for transfusion through the bone marrow of the tibia.

FIG. 3.—Close-up of the arrangement for transfusing through the tibia in the case of a 3-months-old boy with bilateral mastoiditis.

Any of the usual transfusion fluids may be given in this way—saline, Hartmann's solution, blood, serum, or plasma. When using blood it is often necessary to increase the pressure by raising the bottle as much as six feet above the needle; or, alternatively, the blood may be diluted. The constant rate

of drip which can be maintained is usually remarkable; the rate required is adjustable by a screw clip on the tubing. The older the child the larger the marrow cavity and therefore the faster the flow can be. The longest time one transfusion has been maintained was six days. When the needle was taken out it was still firmly held in the bone, and there was no reason to suppose that the transfusion could not have been continued had it been necessary.

Particular attention might be paid to the following points: Emphasis is laid on the necessity for inserting the needle at right angles to the surface of the tibia. This is facilitated by the position of semi-external rotation of the limb. The diagram (Fig. 4) shows the error of attempting to insert the

needle in the antero-posterior direction of the limb, as might happen if the leg were not fixed in the correct position. It is probably wise to inject a small amount of saline through the needle as soon as it has been inserted, to ensure that the marrow has been entered satisfactorily. The adaptor can then be securely connected.

If the needle does work loose, fluid will leak back into the subcutaneous tissues and the limb will become oedematous; the transfusion must then be stopped. A careful watch for oedema should be kept during the first hour or two of the transfusion, because, if oedema is allowed to develop, a pressure necrosis of the skin beneath the flange might result.

Dislodging by kicking with the other leg can be prevented by anchoring it with a handkerchief round the ankle. A small cradle will prevent disturbance by the bed-clothes.

If a second transfusion is required soon after the first has been discontinued the other tibia must of course be employed, as leakage back through the original hole will make that leg impracticable.

It would seem wise to reiterate the need for strict asepsis, since osteomyelitis, though it remains theoretical, is the haunting danger.

The procedure can be facilitated by giving a feed or an appropriate dose of chloral hydrate; these will quiet the baby and often surprisingly help the initial stages of the transfusion.

I want to thank Dr. Donald Paterson and Mr. T. Twistington Higgins for their interest, and Dr. King Lewis for his encouragement and suggestions. The needle and attachments have been made by Messrs. Allen and Hanburys Ltd.

## "CELLOPHANE" FOR THE TREATMENT OF BURNS

BY

JOHN FARR, M.D., F.R.C.S.E.  
Major, R.A.M.C.

Since Davidson's communication in 1925 many other observers have contributed to the literature on the treatment of burns. Usually their methods have had at least two factors in common: first, the exclusion of air, to promote the patient's comfort and to diminish shock and infection; secondly, to allow epithelization to proceed undisturbed by frequent and painful dressings. Within the last three years some observers have emphasized the similarity between the pathology of a burn and that of other wounds, and have reiterated the harm of tissue irritants in the toilet of the burn and demonstrated the value of firm pressure upon the area to support the damaged vascular bed. In the American literature the application of these principles has come to be known as the "cleansing, rest, and compression" treatment of burns. The

work of Allen and Koch (1942) and Siler (1942) has been especially convincing, and their results compel a trial of their methods.

A modification of this form of treatment has been employed in 10 consecutive admissions to a general hospital. The modification advocated is the use of an occlusive dressing medicated with sulphanilamide through which the burned area may be easily inspected. This is achieved by the use of "cellophane" and unguentum sulphanilamidi. The number of cases is unfortunately very small, and there has been no investigation of the blood chemistry or viscosity in the cases studied. All the burns were of the second degree, the average stay in hospital was about 21 days, and all the patients returned to duty. The results have been so uniformly successful that it is thought that a description of this form of treatment will be of value, especially now when the transportation of burned Service personnel presents such problems in the prevention of shock and infection. The use of "cellophane" as a splint for Thiersch grafts has been described by Poth (1942); Ellis (1943) recommends using this material as a dressing for tropical ulcer; but in the literature at my disposal it has not been mentioned as a dressing for burns.

#### Local Treatment of the Burned Area

Using general anaesthesia, the intact skin surrounding the burned area is thoroughly cleaned with white soap and water, and then the toilet of the actual burned area is meticulously carried out. The importance of gentleness and the use of normal saline in irrigating the burned area has been sufficiently stressed in the original papers, but it is well always to remember that "in any burn the vascular bed of the area has been seriously affected."

The medicated sheets of "cellophane" are then applied so that each overlaps the other for about an inch. These sheets adhere to one another and to the intact skin, and the entire burn is embraced in an envelope that permits of easy inspection and prevents contamination. Next, perforated oiled silk is wrapped around the "cellophane." This is not essential, but does help to prevent the wool (which is what we have had to use for compression) from adhering to the dressing and tearing it when removed. The use of sea sponges for compression would probably make such a precaution unnecessary. A firm bandage completes the dressing. After 48 hours the burn is inspected. The "cellophane" may be in some parts blistered by collections of serum. Any such bullae are trimmed away with scissors, and the area affected gently cleaned with saline swabs and another sheet of "cellophane" applied. This transparent dressing adheres lightly to healed burned areas, but if carefully removed does not damage the delicate new epithelium. However, no attempt at removal should be made until it begins to separate itself. The "cellophane" does not adhere to the unhealed areas, so that damage to the tissue, if the dressing must be changed, is minimal.

If the case is received so late that the burn is already frankly infected, a nicety of surgical judgment is demanded. One may try to convert an infected wound into a relatively clean one by prolonged and gentle irrigation (Bisgard *et al.*, 1942) and then rely on the bacteriostatic action of the sulphanilamide to keep the burn clean. Or saline compresses or a Bunyan-Stannard envelope (if available) may be used for 48 hours and the burn then again closed in the "cellophane" envelope.

Some of the patients in this series have arrived many hours after the burn was received and after a prolonged journey in a motor-lorry. In such cases I have usually applied the "cellophane" for 48 hours to avoid the trauma and distress of frequent dressings in an already exhausted patient. If on inspection there is a collection of pus in any one part, the overlying dressing is cut away and saline compresses are applied. The "cellophane" in the uncontaminated areas is left undisturbed and is in no way harmed or made soggy. Usually after 24 or 48 hours these infected areas are clean enough for the "cellophane" to be reapplied, and healing then occurs uneventfully.

#### Preparation of the Dressings

The "cellophane" sheets may be medicated, sterilized, and read for immediate use when needed, or the unguentum

sulphanilamidi (sulphathiazole has not been available to me) may be spread on the sterile sheets of "cellophane" just before their application. All types of transparent wood-pulp tissue have been used, and have all been salvage. The paper is sterilized by first dusting with talc and then autoclaving for 20 minutes at 15 lb. The talc is then dusted off and the "cellophane" is placed flat on a sterile towel and a thin layer of unguentum sulphanilamidi 10% is spread on. It is then folded four times, with the non-medicated surface to the outside. Several such pieces are sealed in a conveniently sized tin and are always available for immediate use.

#### First-aid Measure

It is suggested that the application of a powdered sulphonamide to the burn or wound, followed by the immediate application of "cellophane" sterilized by boiling, offers many advantages. It permits of easy and painless inspection of the burn when the patient reaches the centre and the ultimate treatment has to be decided, and does not in any way prejudice the form of treatment to be adopted. It would prevent contamination and be bacteriostatic to infection already present in the burn. A dressing of this type is available almost anywhere.

An even more simple measure which could be applied in very forward areas when no medical equipment is available should be considered. In such circumstances the "cellophane" wrapping of a cigarette package could be applied to the burn, for its inner surface is almost certainly sterile; such a dressing would be comfortable and adequate until the patient was able to receive further treatment.

The satisfactory results achieved in this series were, as stated, all in second-degree burns. In third-degree burns, as always, treatment should be directed to preparing the burned area for skin-grafting, and the dressing would be of temporary value only.

This paper is published with the kind permission of my officer commanding, Col. David Bell, O.B.E., E.A.A.M.C.

## SYMPTOMLESS ENLARGEMENT OF THE OESOPHAGUS

BY

JOHN L. D'SILVA, D.Sc., M.R.C.P.

Assistant Physician, E.M.S.; Chief Assistant, St. Bartholomew's Hospital

Many cases of enlargement of the oesophagus are on record, but these have all been associated with symptoms which led directly to the investigation of the oesophagus. The condition occurs over a wide range of age groups, and is believed to be secondary to achalasia of the cardia or to organic obstruction of the lower end of the oesophagus. In the case now to be described there were no symptoms, and the condition was discovered as a result of the usual routine examination of the chest.

#### Case History

A commercial traveller aged 57 was admitted to hospital on Aug. 29, 1941, complaining of pain in the joints; a diagnosis of rheumatoid arthritis was made. He did not complain of gastro-intestinal symptoms and had never had dysphagia, unexplained vomiting, regurgitation of food, or pain behind the xiphoid. There were no respiratory symptoms and he had not lost weight.

On examination of the chest the only abnormality found anteriorly was slightly increased vocal resonance in the right midzone. Posteriorly, abnormal signs were confined to the right base, where vocal fremitus was lessened, the percussion note impaired, breath sounds vesicular but diminished in intensity, and vocal resonance reduced. Movements of both sides of the chest were equal and there was no evidence of displacement of the mediastinum. The blood pressure was 118/68.

A plain radiograph of the lung fields showed a triangular shadow extending to the right of the right border of the sternum from above the level of the aortic knuckle to the convexity of the right dome of the diaphragm. A barium swallow revealed a grossly enlarged oesophagus (see Fig.). The shape of the lower end of the organ

could be seen only in an oblique view. The oesophagus was grossly elongated so that it was obliged to kink, the kink resting on the right cupola of the diaphragm. The terminal portion of the tube narrowed gradually to pass to the cardia by a fairly narrow channel which appeared to offer considerable resistance to the passage of barium. Three-quarters of a cupful of barium emulsion passed into the stomach within 30 minutes, and peristaltic waves were observed emptying emulsion from the oesophagus into the stomach. In an hour a trace of barium remained in the lower end of the oesophagus.

The radiological appearances did not alter over a period of 15 months, and now, two years after the condition was diagnosed, the patient is symptom-free. A barium follow-through showed no abnormality of the stomach or colon (cf. Etzel, 1937).

### Discussion

Cases of dilated oesophagus described in the literature have usually been associated with achalasia of the cardia, a condition thought by Hurst (Hurst, 1914-15; Hurst and Rake, 1929-30), and also Rolleston (1896), to be due to an upset in the neuro-muscular mechanism in the region of the cardia. Hurst visualized food being propelled down the oesophagus to be held up at the cardia, which did not relax. In consequence the oesophagus dilated to accommodate the food, and in time this resulted in a permanent dilatation of the organ. There was no question of paralytic dilatation, because violent, frequent, and ineffectual peristaltic movements were observed in the oesophagus.

All cases of achalasia of the cardia which have been examined histologically have shown inflammatory changes and fibrosis affecting the ganglion cells of Auerbach's plexus (Rake 1927, and others). Many cases of achalasia are on record in which no histological examinations have been reported; but they are all cases which showed symptoms of obstruction, and there is no good reason to separate them from the above group.

It has been assumed hitherto that dilatation of the oesophagus in these cases was a consequence of the functional defect at the cardia, supporting evidence being some diminution in size following surgical relief of the functional obstruction. There is no record of an oesophagus normal in size before the onset of symptoms. This point is important because of the present case.

Apart from those cases with marked symptoms in which the diagnosis seemed probable on clinical examination alone, cases have been described with slight symptoms of obstruction but with well-marked radiographic changes (Shelburne, 1934; Belot and Nahan, 1936; Becquet, 1938); and a similar condition in children may be associated with considerable oesophageal dilatation (Rolleston, 1896; Cameron, 1927; Negus, 1936). Besides, there appears to be no direct relationship between the degree

of obstruction and the extent of oesophageal dilatation (Brown Kelly, 1912), and oesophageal stenosis due to a neoplasm or fibrous stricture may not be associated with gross dilatation.

In the case here described there is delay in the emptying of the oesophagus, but some barium entered the stomach very rapidly and each peristaltic wave was associated with the passage of barium. The degree of achalasia, if any exists, must be minimal; more probably the delay should be attributed to the tortuous course followed by the oesophagus.

In the absence of histological material for study it is difficult to assign this case to a definite group, but it differs from what has been described as achalasia of the cardia, in the absence of symptoms, the absence of any evidence of spasm, and the abnormal shape and length of the oesophagus. It is difficult to make a reasonable suggestion as to its cause unless the issue be evaded by ascribing it to a "congenital defect." Experimental evidence which might have a bearing on the aetiology of this condition is meagre, but the following observations should be mentioned:

(a) McCarrison (1919) has described the effects of chronic hypovitaminosis-B on pigeons. The changes in Auerbach's plexus resemble those found in achalasia. The state of vitamin-B saturation of this patient has not been determined, but he exhibited no signs of vitamin-B lack.

(b) Experimentally, in animals, bilateral vagotomy led only to a temporary absence of peristalsis (and hence delayed emptying) in the oesophagus (Cannon, 1906-7), but when the longitudinal muscle coat was stripped from the subdiaphragmatic portion enlargement of the oesophagus resulted (cf. Netto and Etzel, 1934). The latter operation always resulted in the simultaneous removal of Auerbach's plexus, thus providing some direct evidence that enlargement of the oesophagus can follow damage to this plexus.

The cause of the oesophageal enlargement in this case is therefore obscure; there is no direct evidence as to its aetiology, but a congenital defect of the longitudinal muscle fibres is possible.

I am indebted to Prof. R. V. Christie for permission to publish this case, and for his helpful criticisms of this paper.

## Medical Memoranda

### Alternative Method of Treatment for Late Cases of Strangulated Femoral Hernia

Owing to the very high mortality associated with late cases of strangulated femoral hernia it is of interest to describe an alternative treatment which has proved successful. While not in any way decrying the standard treatment, there are no doubt many late cases to which the technique to be described could be applied. These patients are very dehydrated and exhausted; therefore it is essential to keep to the minimum the amount of manipulation at any one time.

#### CASE RECORD

Mrs. A., aged 69, was admitted to hospital with a 5-day history of abdominal pain, vomiting, and increasing distension. Just before the onset of her symptoms a lump had appeared in the right groin, following a strain. On examination the patient looked very ill; temperature 99.8° F., pulse 110. Her face was ashen and appeared sunken, her tongue was dry and furred, and she was obviously very dehydrated. She complained greatly of thirst, and her mind seemed to be rather confused. There had been no action of the bowels for seven days. Examination of the abdomen revealed marked distension, with a large red tender swelling in the right groin, no doubt containing sloughing bowel and pus. Intravenous saline was begun immediately and the patient brought to the operating theatre. Under pentothal anaesthesia a small median subumbilical incision was

sulphadiazine; and penicillin, which may easily supplant sulphonamides in the not too distant future, is not even mentioned. Sulphathiazole is the drug recommended, and the optimum dosage is given as 4 g. daily for five days, with which few will quarrel; the giving of the drug continuously for ten days, even in reduced dosage, will meet with less general agreement. When failure of cure occurs with one or two courses of sulphathiazole, injections of large doses of gonococcal vaccine are recommended, such as 600 to 800 millions, combined with oral sulphathiazole; these should produce a local reaction four to six inches in diameter and an elevation of temperature of one or two degrees. If the author had met more of the really sulphonamide-resistant cases now occurring in various parts of the world he might usefully have said more concerning their treatment; when penicillin is not available they often are the despair of the venereologist.

One suggestion is that all pathological reports should, like serum tests, be returned as "positive," "doubtful," or "negative"; there is much to be said for this, especially if, as Dr. Herrold suggests, the pathologist adds any special remarks which are likely to be helpful to the clinician. The statement on page 88 under "Epidemiology" that "at least 10% of all infections in the male are followed by a two- or three-month period of infectivity, with few or no clinical symptoms" requires confirmation; if this means that 10% of apparently cured cases remain infective for two or three months, many venereologists would disagree. Apparently prophylaxis not only for Service men but for civilians is recommended; a warning is wisely uttered against the use of oral sulphonamides for this purpose. The last chapter contains 62 case histories illustrative of certain points, and there is a long list of references.

This is a useful but not outstanding publication; the subject lends itself rather to the form of a pamphlet, which can be reprinted frequently with amendments, than to a book.

### MEDICAL MYCOLOGY

*Elements of Medical Mycology.* By J. H. Swartz, M.D. Introduction by F.D. Weidman, M.D. (Pp. 190; large folding chart. 21s.) London: William Heinemann.

This is a very useful little book, and can be recommended especially to the laboratory worker. It makes a somewhat different approach to the subject from what is usual in medical works on this subject, for it adopts a botanical rather than a clinical attitude. There are useful tables showing the place of the various pathogenic fungi among the Fungaceae as a whole, and Dr. Swartz takes the trouble to define the various terms, such as sterigma, chlamydospore, fuseaux, etc., which may be familiar to the real mycologist but prove a stumbling-block to the inquiring mind of the ordinary doctor. These definitions are clarified by diagrams, and it must be added that the numerous photomicrographs with which this book is copiously illustrated are also a great help.

On the clinical side the author has given more consideration to treatment than to diagnosis, and there is a full discussion of the management of dermatophytosis, a subject which includes all the commoner forms of mycotic infection of the skin, such as "dhotie itch" and "athlete's foot," and the various "id" eruptions, which are manifestations of cutaneous allergy to an active focus of fungus infection. We are glad to notice that Dr. Swartz emphasizes the desirability of gentle measures in almost all cases. He mentions one remedy of which we do not remember to have heard before, and that is the inhalation of ethyl iodide; he says it is valuable in stubborn cases, but when using it certain precautions are necessary.

A very practical little book, and just as useful to most medical practitioners as many more expensive and ambitious volumes on this subject.

### Notes on Books

*The Road to Maturity* (Victor Gollancz; 6s.) is one of the best if not the best book yet published on the subject of sex education. As Sir Richard Livingstone says in the foreword: "It sees sex as a whole; as a purely natural phenomenon with definite physical facts and laws, and as a force involving some of the highest spiritual faculties of man. It makes the problem clear, suggests definite

methods for solving it." Dr. EDWARD F. GRIFFITH edits the book and himself contributes the framework. Several authorities, including those with practical experience as heads of both boys' and girls' schools, contribute chapters, and Dr. Noel Harris writes a chapter on psychological types. Perhaps the most valuable part of the book is Part 2, which comprises the text of three lectures given to boys of secondary school age, at puberty, at about sixteen, and just before they leave. Medical men and women have a very considerable responsibility both in giving sex education themselves and in advising others who may be called upon to do the actual job. They will find this book an enormous help in clarifying their ideas and giving valuable suggestions as to how to set about this difficult task. No doubt there is nothing that they will not have known before, but to know a subject and to put it across effectively are not the same thing.

An illustrated pamphlet, *Sokol: the Czechoslovak National Gymnastic Organization*, by F. A. TOUFAR, a member of the Sokol instructors' staff in London, has been published at 6d. by George Allen and Unwin. Here will be found an account of the origin and growth of the movement from a small gymnastic society into a national organization inspired by a powerful national sentiment.

The second edition of Dr. I. SIMSON HALL's book *Diseases of the Nose, Throat and Ear* was reviewed in these columns on Dec. 20, 1941. It is now followed by a third edition (E. and S. Livingstone; 15s.), for which the subject-matter has been revised and brought up to date and some new plates and diagrams added. A feature of the book is its illustrations, of which eight are coloured plates.

## Preparations and Appliances

### A RECONSTRUCTED EAR SYRINGE

Dr. PERCY TATCHELL writes:

When a rubber ear syringe wears out to-day it is rather hard to replace the rubber; but there are plenty of old tennis balls about. If a discarded syringe is pulled to pieces, a large washer will be found inside screwed on to the stem to keep the latter fixed; it is put there by the makers before the two halves of the ball are vulcanized up. The puzzle is how, having got the washer inside the tennis ball, to screw it on to the nozzle. At first sight this looks impossible, but the thing that makes it feasible is a piece of very soft wire about 6 in. long: copper would do, but electric fuse wire is ideal.

First burn a hole in the tennis ball with a red-hot iron of the right size to admit the screw of the stem—an old rat-tail file will answer the purpose. Next twist up a "foot" on the end of the wire to make a lifter (Fig. 1), of such a size as will pass

through the hole; and, having passed it into the ball, thread on the washer to the wire; then tipping the washer on end, still keeping it threaded, squeeze it through the hole, which has been compressed to a slit by side pressure. The washer will fall to the bottom of the ball, and lie on the foot of the wire lifter. By raising the wire the washer will be seen immediately under the hole. If the stem of the syringe is now also threaded on the wire, the appearance will be as shown in Fig. 2.

Pass the stem on down into the hole, and by wriggling the wire the threaded part will eventually be felt to engage in the washer; and having been previously soaped it can be easily screwed up tight: the slight pressure against the inner side of the ball prevents the washer from rotating. Then comes the great moment: a sharp pull on the soft wire; it straightens, and out it comes. (Fig. 3.)

If you are a little doubtful of the asepticity of the ball, it can be flamed and painted.

# BROMETHOL B.D.H.

## *The Basal Anaesthetic for Rectal Injection*

The induction of anaesthesia with Bromethol B.D.H. (Bromethol B.P.) has many outstanding advantages. Among these are:—

- for the patient, elimination of apprehension at induction and absence of post-operative nausea and vomiting
- for the anaesthetist, easy induction and maintenance with nitrous oxide-oxygen
- for the surgeon, adequate relaxation of muscles and minimum cerebral congestion.

Recently the prices of Bromethol B.D.H. have been reduced substantially, the reduced prices being those given below.

Bottles of 25 c.c. . . . 8s. 1d.  
 Bottles of 100 c.c. . . . 27s. 0d.

# FOR ALL TYPES OF FUNGUS DISEASES OF THE SKIN

● While almost specific in psoriasis, 'Derobin' is also effective in all fungus diseases of the skin, particularly the more chronic and resistant forms. It is best applied as an ointment in strengths of 0.25 to 3 per cent and, where the skin is scaly, it is advantageous to incorporate salicylic acid.

'Derobin' is compatible with the medicaments commonly used in dermatology.

## PHILIPS MOBILE 'D' DIAGNOSTIC X-RAY UNITS

This fine 90/30 Mobile X-Ray Unit, ideal for ward use and for emergency purposes, is widely recognised as the foremost equipment of its class. Modern in design and conception and manufactured in large series, it incorporates numerous outstanding technical advantages which are described in full in publication XMI, available on request. In radiographic performance the MOBILE 'D' is superb and, above all, it is thoroughly reliable. Authorised purchasers will find this equipment a highly satisfactory investment. Enquiries are invited.

## SURGERY IN THE EIGHTH ARMY

In these days of momentous happenings some of the less spectacular achievements of our Army, which at another time would command much attention, are liable to fade into relative obscurity. For this reason a review of certain aspects of the work of the Medical Services with the Eighth Army during its advance from el Alamein to Italy, which concludes in this number of the *Journal*, is to be welcomed as a permanent record of an evolutionary phase in military medicine which presents many features of great interest. Brigadier Charles Donald draws a vivid picture of the scene from the point of view of a consultant surgeon who is as deeply concerned with questions of tents and beds, the location of skilled surgeons and nurses, and the optimum disposal of the wounded man, as with details of surgical technique.

Each theatre of war has its own characteristics which control its development and present it with its own peculiar problems. In this campaign sandstorms, heat, shortage of water, flies, mosquitoes, all played their part; but the dominating feature which, particularly in the African phases, influenced every decision and plan was the weary length of the communications. The further the Army advanced the longer became the journey the wounded man had to make to the base hospital, much of it in ambulance cars over open desert and tracks of a degree of roughness which beggars description and which made the journey an ordeal. This was brought painfully to notice in the pre-Alamein phases of the Middle East war, when fighting ebbed and flowed between the Egyptian frontier and Benghazi, and many lessons were learnt which found successful application in the period now under review. The most important of these was that surgery and other specialized treatment must be brought forward to the patient as near the fighting line as possible. This decision led to the development of mobile units, such as the surgical team (precursor of the modern field surgical unit) and the field transfusion unit, both of which worked wherever their services were required from casualty clearing station to forward field ambulance; and of other special surgical units which functioned up to casualty clearing station level. Casualty clearing stations, the most forward units with facilities for holding patients, had in their turn to acquire a hitherto unknown degree of mobility, and be prepared to move at the shortest notice. By splitting them into heavy and light sections further elasticity was attained, and units "leap-frogged" over one another in such a way that a continuous chain of staging posts was maintained from front to base. But it is not sufficient merely to provide surgery; it has to be the best surgery of its kind, for at

no other stage is skilled treatment so richly rewarded, or indifferent treatment more liable to be followed by complications and delay in healing, if nothing worse. Brigadier Donald wisely stresses the fact that military surgery in such surroundings, crude though it may appear at first sight to the new arrival from a fully equipped hospital working under peace conditions, is none the less an art in itself, in which skill and experience are just as essential to achieve the best results as in any other type of surgery. The policy of putting young surgeons through a term of apprenticeship in a base hospital under the tuition of officers with forward experience, and later in a staging post on the lines of communication, before passing them on to field units, is one that has much to commend it, as is the appointment of an experienced consultant to devote himself to the control of forward surgery, and to ensuring that the right man is in the right place.

As experience ripened, the build-up of an advanced operating centre forward of a casualty clearing station became more or less standardized as two surgical teams and a field transfusion unit attached to the main dressing station of a field ambulance (the new unit, the field dressing station, had not then been introduced in the Middle East Force). Of the special surgical units the orthopaedic team, because of the long periods its patients had to remain under observation and treatment, found no place in forward areas, where "all surgeons must be orthopaedists up to a point." On the other hand, an experimental grouping of sections of a maxillo-facial and a neurosurgical team with an ophthalmic team proved a striking success, and thereafter this "unholy trinity" were kept together, usually at a casualty clearing station, working in the closest co-operation and usually in the same theatre. Chest teams were not brought right forward, the policy being to maintain one at an advanced general hospital. With this chain of units disposed as close to the fighting line as circumstances would permit, the standard and scope of the treatment afforded to the wounded man reached a high level.

To the transfusion service Brigadier Donald pays a generous tribute. The officer of the field transfusion unit, working constantly in company with his colleagues of the surgical teams, in most cases took over the management of the pre-operative ward in addition to his duties as resuscitation officer, and became an integral part of the team. Such an arrangement has everything to recommend it. Perhaps the most valuable contribution which the transfusion service made to the advancement of its efficiency was the system of supply which it developed. It became apparent that distribution must be controlled by personnel specially nominated for this purpose, and a field transfusion unit, equipped with additional transport, was detailed to provide one or more "advanced blood banks" and to institute a "door-to-door" delivery of transfusion equipment and fluids. The results were eminently satisfactory. Mention might also be made of the "travelling transfusion" devised by Captain Lucas<sup>1</sup> which in many cases proved of vital importance in maintaining the condition of seriously wounded men in transit from one unit to another.

<sup>1</sup> *Lancet*, 1943, 2, 503.

With all these facilities available, and a lengthy line of communication stretching behind to the base hospital, the decision when to evacuate and when to hold the patient often became an acute one. Administrative officers, with their eye on future commitments, had perforce to urge evacuation where the surgeon, for the patient's sake, would fain have retained him. Compromise was effected, and selected serious cases, amounting to from 3 to 5%, were retained where they were operated on, while the remainder passed on down the chain of staging posts till the base was reached. The dictum that "no one is fit for the air who is not fit for the road" may surprise those whose experience of air travel is limited to peacetime conditions and who have visualized the smooth and rapid air journey as the ideal method of transporting wounded. In a forward area the disadvantages of air evacuation for the very seriously wounded lie not in the air journey but in the rough passage by road between hospital and aerodrome, and, once there, in the inevitable and often protracted delay, with limited nursing facilities, before the patient can be emplaned. Nevertheless many thousands of selected sick and wounded were transported to the base in this way. Air evacuation proved specially useful for post-operative patients who, though fit to travel, could not stand a prolonged journey.

To all who served in the last war it will be obvious that the conditions which then obtained in France and Flanders bear little or no resemblance to those in which the Eighth Army operated. One was a static war: the other essentially a war of movement, in which mobility, elasticity, and adaptability were the all-important keynotes. Though the operations which lie before us will no doubt cover the ground occupied in 1914-18, the *tempo* is more likely to be that of the mobile warfare experienced by the Eighth Army, so that their experiences and the methods which they developed are worthy of close study. Modifications designed to afford greater mobility and flexibility have recently been introduced into the structure and establishment of medical field units, and it can be confidently anticipated that the lot of the wounded man will be made easier by the application of the principles which have been defined and the methods which have been evolved in these recent campaigns.

### DEPARTMENTAL PRESCRIPTION

A recent pamphlet issued by the Ministries of Food and Health, with the approval of the Food Rationing (Special Diets) Advisory Committee of the Medical Research Council, is entitled "Diets for Patients with Ulcers of the Stomach and Duodenum," and it is being sent to every general practitioner and to hospital staffs and others professionally interested. It deals with maintenance diets for patients with ulcers under wartime restrictions and not with the acute stage of the disease. Modern dietetic treatment of peptic ulcer is based on the work of Sippy, whose diets were high in milk and fat. Between the two wars a too-strict Sippy diet proved to be one of the most important causes of scurvy, and the diet was therefore progressively modified

by the addition of puréed vegetables and fruits and fruit juices. As a result the provision of frequent feeds of pul-taceous material, containing the essential nutritive principles and vitamins, became more important than a narrow preoccupation with the acid-lowering properties of milk and fats. This phase of development has undoubtedly eased the transition to the war period, during which milk is restricted to two pints a day, and eggs and fats are not freely available. This innocent-looking document does nevertheless raise certain major controversial issues, for the problems of dietetics in wartime soon bring us face to face with the control of a free profession. We are told that further copies of the pamphlet may be obtained from the Public Relations Division of the Ministry of Health, which is not a place medical men naturally turn to for information. A Public Relations Department is in effect a Government advertising agency, and advertisement, whether of patent medicines or Government Departments, is equally suspect to the profession. In fact, many doctors do not take at all kindly to instruction in the treatment of disease by the Ministry of Health or the Ministry of Food, as a letter in our issue of May 20 (p. 701) showed.

Wing Cmdr. Stanley Turner and his colleagues who signed the letter referred to perhaps rather overstate the case against the bureaucrat, who during this war has completely ousted Aunt Sally from popular disfavour. The two have one thing in common—not being allowed to defend themselves—and we think that the severe criticism of the Ministry of Food by Wing Cmdr. Turner and his colleagues might have been tempered with some recognition of the stupendous difficulties confronting the Ministry in this war and the phenomenal success which has attended its efforts in overcoming them. It is obvious that the doctor's freedom to prescribe diets for his patients in wartime is limited by the food that is available. It will be granted that in peacetime the prescription of a special diet is often the result of applying the art of medicine rather than of working according to the objective findings of the clinical pathologist and the biochemist. In the practice of medicine, where knowledge is so inexact, where, as Sir Thomas Lewis has put it recently,<sup>1</sup> "the idea that certain diseases are fully understood is an illusion," it is not necessarily a sign of wisdom to put more faith in the findings of the laboratory than in the observations at the bedside. Nevertheless in wartime the doctor, along with the rest of the population, has to submit to the administrator—and with as good a grace as possible. The administrator must necessarily try to grasp something which is tangible, and so will ask the practitioner who wants to have special rations for a patient with gout to give him some figures to go on—namely, estimations of blood uric acid. But the administrator is constitutionally incapable of understanding the point of view of the practising doctor, just as the latter also finds it difficult to see things through what appear to him to be the myopic spectacles of that fearful creature called the bureaucrat. Earlier in the war the Ministry of Food asked the doctor who wanted extra milk for his patient to hand the certificate to the householder, stating on it the disease the patient was suffering from. To get

<sup>1</sup> *Lancet*, May 13, p. 619.

the extra milk the householder had to pass the certificate to the milkman. That this procedure broke the professional confidence between patient and doctor, that it would entail endless personal embarrassment and distress to the tuberculous person whose condition would become divulged to the whole neighbourhood through the traditionally communicative milkman, quite plainly never occurred to the minds of the responsible officials issuing the order. A similar lack of imagination is behind the requirement to the practitioner to submit to a local food office the evidence of his diagnosis. The interval during which patient and doctor wait to have the diagnosis confirmed must be highly embarrassing to both. The disclosure of the condition diagnosed to the small chain of officials in the local food office must no doubt offer them a topic of conversation, and on a dull day no doubt a little harmless betting on the ultimate diagnosis transmitted through the usual channels might relieve the local administrative tedium. In wartime some control is necessary, but we refuse to believe that any system of control which is based upon distrust of the practising doctor can help either his patient or himself. Doctors rightly regard this sort of thing as intolerable. It is not possible to conduct the practice of medicine by orders, regulations, or departmental circulars.

All this is an illustration of what medical men at the moment fear from a projected national health service which would bring the control of the practice of personal medicine under local authorities and the Ministry of Health. We may be sure that the dietetic information in the pamphlet issued by the two Ministries is sound, because it comes from the Medical Research Council. But we question the justification for the issue of such a pamphlet by two Ministries which have no place in the field of personal medicine and which indeed in this case seem to be acting simply as medical publishers. But it is less for what it is than for what it portends that we debate this matter. Domiciliary medicine can never be efficiently practised on any other than an individual basis—that is to say, there must be complete freedom between the doctor and the patient to tackle a personal problem unobstructed by a third authority. There are already enough hindrances to the solution of the individual problem of the diseased person. There may be, first and most important, limitation of knowledge; secondly, there may be imperfect accord between doctor and patient; thirdly, there may be and often are all those obstacles to good health comprehended under the term "poverty." A fourth and formidable risk is that of making a mistake on a large scale. The individual doctor errs often enough, because he is constituted as his fellows are. But the kind of action now taken by the two Ministries, if persisted in in peacetime, may enforce and perpetuate error on a wide scale. Essentially, the control of the practice of personal medicine can be exercised through one channel only, and that is the channel of education; an education which must continue throughout the doctor's working life. And unless his conditions of work and the payment he receives for it provide him with time in which to read and reflect, then such an educative process cannot be continued; but the remedy is certainly not "medicine by circular."

### DUST IN THE FOUNDRY

The foundry has long had the reputation of being a dusty place, but it has been difficult to assess the extent to which it affects the health of persons employed in it. A report<sup>1</sup> published by the Industrial Welfare Division of the Department of Labour and National Service of the Commonwealth of Australia carries a stage further the work done in New South Wales by Dr. Charles Badham and his co-workers. The risk to the health of foundry workers consists in damage to the lungs by dust, and in view of the variety of processes involving exposure to different kinds of dust—including silica, silicates, iron, carbundum, and coal—and different concentrations of dust varying from moment to moment throughout the working day, the problem is complicated. The overriding difficulty of evaluation is concerned with the latent period before the evils of exposure show themselves in the form of recognizable pulmonary disease, whether as definite silicosis or as another form of pneumoconiosis. In this study measurement of the air-borne dust was made by taking snap samples with the Owens dust counter to provide estimates of the numbers of dust particles in a given volume of air; but the snap samples were taken at intervals during the series of phases in a process and the time periods measured for each phase. From these data an average exposure was calculated and expressed in terms of particle-hours per c.c.m. Thus, in a machine-moulding operation the mean particle concentration per c.c.m. varied between 100 and 1,605 in the different phases of the operation, and the duration of each phase varied between 70 and 480 seconds per hour. The resulting average exposure for this operation was 163.9 particle-hours per c.c.m. Similar observations were made at the seven foundries investigated, and comparisons could be made to indicate the relative risks as between operations, phases of operations, and these carried out in the different foundries. The operations studied in this way included moulding, shaking-out, sand-conditioning, and cleaning of the castings by blasting, rumbling, brushing, grinding, and chipping. For determining the composition of the air-borne dusts samples were collected by means of the Greenburg-Smith impinger, and these were submitted to chemical analysis. The most important single result of these analyses was the determination of the proportion of free silica in the dust. From observation of the lay-out, plant housekeeping, and ventilation provided in the seven foundries included in this study, and from the data obtained from the dust estimations and analyses, it is suggested that a dust exposure of 500 particle-hours per c.c.m. is a practical working standard for the foundry industry, with the proviso that where the dust contains more than 50% of free silica the average exposure should not exceed 200 particle-hours per c.c.m. It is not suggested that this standard would obviate any danger of developing silicosis or fibrosis, but that by its adoption the working conditions in foundries will be vastly improved.

This technical study was not expected to give an indication of dust concentrations which could be regarded as safe for workers; this is a medical question, and a statement on safe conditions could best be made as the result of a correlation of such dust estimations with medical examinations of workers who had been engaged for suitable periods of employment in the different processes, arranged to give satisfactory statistical data and to include clinical and radiological examinations.

<sup>1</sup> *Dust Hazards in Australian Foundries*, by A. A. Ross and N. H. Shaw. Technical Report No. 1, Industrial Welfare Division, Department of Labour and National Service, Commonwealth of Australia, 1943.

## DIAGNOSIS AND TREATMENT OF DELINQUENCY

Since its foundation in 1932 the Institute for the Scientific Treatment of Delinquency has made steady progress. Dr. Edward Glover, the chairman of its scientific committee and a co-director of its psychopathic clinic, has reported on its work during the five years from 1937 to 1941 in a pamphlet entitled "The Diagnosis and Treatment of Delinquency" and published by the Institute. It forms a chapter in *Mental Abnormality and Crime*, the second volume of "English Studies in Criminal Science," to be published shortly by Macmillans. Most of the cases come from the police courts, but a large number are referred by medical practitioners, other psychological clinics, and philanthropic societies. The Institute has had to contend with many obstacles. During the "blitz" a time bomb put the clinic out of action for several weeks and ultimately forced it to move; all the juvenile courts but one closed for a period; war work made it extremely difficult for probationers to attend for treatment during the day; and many of the most active members of the staff went to the war. The work has, however, been continued. Each patient is seen as soon as possible after referral, by a psychiatric social worker, a medical psychologist, an educational psychologist, and a physician—also, if necessary, by another psychiatrist, a vocational guidance officer, and a variety of organic specialists. The director co-ordinates the various findings and gives his provisional diagnosis in non-technical language for the court or whoever else has referred the patient. He keeps constantly in mind not only the difficulty magistrates may have in giving expression to the essentially clinical findings of the Institute, but also the practical difficulties court officials may encounter when seeking to administer court decisions. The patient's need of psychological treatment may conflict with the need for segregation or close supervision; the patient may require psychological treatment and at the same time special employment which he cannot get near the clinic. Many of these difficulties could be overcome by the provision of hostels under the Institute's control. The ultimate disposal of the patient is a matter for the court, and even if the court acts on the recommendation of the Institute treatment may be prevented by social or domestic obstacles. In 1940 and 1941 a little over half the new cases were recommended treatment, but hardly one-third actually received it. Nevertheless, each year an increasing number of delinquents are put on probation with the condition that they undergo psychological treatment. The number of school children sent to the clinic has grown apace, many of them having been returned from reception areas as "unbilletable." They have mostly been placed in new or more suitable foster homes, preferably within reach of a child-guidance clinic. Much of the actual work of disposal is done by the psychiatric social worker, Miss M. Wilcox. This work has real therapeutic value, and staff permitted could be amplified in almost every direction. The figures for results show a recovery rate of about one in ten and an "improved" rate of about two-fifths of those discharged, but the number of discharges through circumstances outside the control of the clinic is very high.

Taking everything into account, the Institute's work is clearly justified and admirable. Dr. Glover declares that it is urgently necessary to enlarge the technical and administrative staff. Apart from that, the usefulness of the Institute would be greatly increased, he says, by a variety of extensions of activity: the provision of a suitable hostel in London, the organization of an observation centre outside London, a scheme of special staff training, research, team conferences, and seminars for magistrates and clerks. All this, however, requires money and exten-

sive publicity. The Institute finds it harder to achieve a sound economic basis than to overcome the difficulties of its work. Reliance on voluntary contributions now limits its usefulness, and the time has come when the contribution it is making to society should be recognized by an adequate grant from public funds.

## THE PHARMACEUTICAL SOCIETY'S COLLEGE

The Pharmaceutical Society has published a report of research work carried out in its College during the period January, 1942, to June, 1943. As in other research institutions the staff and the facilities for investigation have been seriously diminished by the war, but nevertheless the report indicates that much useful work continues.

Perhaps the most interesting development from the medical point of view concerns the hormone of the suprarenal cortex. Dr. Marthe Vogt, in the department of pharmacology, has succeeded in demonstrating the presence of cortical hormone in blood taken from the dog's suprarenal vein. She measures the amount of hormone in blood by its power to prolong the life of young adrenalectomized rats exposed to low temperature, the prolongation being proportional to the amount present. Dr. Vogt finds the hormone in blood from the suprarenal vein, but not in arterial blood or in blood from the right side of the heart. The amount of hormone issuing from the gland is large. One millilitre of a commercial extract of suprarenal cortex contains the activity present in 75 g. gland, yet the average output of hormone from one dog's suprarenal gland per minute per kg. of body weight was equivalent to 0.6 g. gland. Assuming a dog of 10 kg. with two suprarenal glands, this means that a dog liberates in its blood activity equal to 1 millilitre of commercial extract in so short a period as 6 minutes. It is not a matter for surprise, therefore, that clinicians find cortical extract to be weak or transitory in effect. This work opens up a new approach to the study of the cortical hormone which promises to be extremely fruitful, and the Pharmaceutical Society is to be congratulated on this important development. Another investigation of much technical difficulty carried out by Dr. Vogt concerned the pathway of the impulses which lead to ovulation in the rabbit. The rabbit ovulates within a few hours after copulation, and ovulation is due to a secretion from the anterior lobe. What is the path of the nervous impulses set up by the act of copulation which cause the discharge of this secretion? Earlier work showed that the sympathetic is not involved. Experiments in which the greater superficial petrosal nerve was destroyed on both sides have now been carried out and have shown that this channel is not involved either. Probably, therefore, the anterior lobe is innervated, like the posterior lobe, by way of the supra-optico-hypophysial tract.

In the department of pharmaceutical chemistry further studies on acridine compounds have been made under Dr. W. H. Linnell's direction, and a number of chloro-derivatives of amino-acridines have been prepared for the first time. They were, however, less active as bactericidal agents than the amino-acridines from which they were prepared. Work has also been done on isomers of stilboestrol, and on derivatives of chlorocresol in the hope of finding a powerful water-soluble disinfectant. Hand in hand with this work the department of pharmaceuticals under Mr. H. Berry has investigated the variation in the bactericidal value of lysol according to the soap used to dissolve it.

We much regret to announce the death of Sir Cuthbert Wallace, Bart., K.C.M.G., C.B., former President of the Royal College of Surgeons of England and consulting surgeon to St. Thomas's Hospital.

## RESEARCH AND GENERAL PRACTICE THE END-RESULTS OF TREATMENT

BY

C. E. S. FLEMING, M.R.C.S.

On all sides we are being told that, in order to improve the country's medical services, medical research should be greatly increased and advanced. Subsidized by the Government, this would demand buildings, equipment, specially qualified investigators, all at a considerable cost. There is, however, possible another form of research, requiring none of these adjuncts, only approval, keenness, aptitude, and opportunity. It is an intensive inquiry into subjects which general practitioners have peculiar opportunities for investigating, and it could be undertaken by them in conjunction with their everyday practice. The work would not, of course, be in any way compulsory or a duty; just another facet in the many-sided outlook of a doctor's life, an outlook that has been casually used by most of them, but not methodically or persistently—the working out of problems that occur almost daily. It is a desire for a further and more complete knowledge about much that confronts the practitioner, which though latent in all his work has not been generally recognized as coming definitely within the ambit of his practice.

A form of research that must of necessity be observational is apt to be depreciated as not being truly scientific, yet it has in the past yielded results very valuable from the clinical point of view. As a study it must develop naturally and by degrees, fostered by a doctor's desire, with the encouragement, inspiration, and assistance of teachers, hospitals, laboratory workers, and others.

### The Patient at Home

When a doctor starts practice he finds it difficult to recognize his patient as the same that he knew in the ward in charge of a nurse. He finds him and his family living under conditions he really knew little of—quite a new problem. He wonders whether the treatment he has seen succeed in the ward can be properly and successfully carried out in the patient's home. He begins to doubt, wants to know more of the condition that may influence his treatment, the chance of direction given in regard to rest, quiet, diet, and so on being properly carried out. He wants to know not only all the factors of the experiment which he considers every treatment to be, but also the result—the real tested result—of the experiment.

There must be many in like perplexity—men willing and with the aptitude to make inquiries and evaluate the results. For it is the family doctor more than any other who has the opportunity not only of seeing the very beginning of disease and what led to it but also of proving the real value, the end-result of treatment, and who, living as he does in close contact with his patients, is most likely to deplore the too-frequent failures of treatment and want to know the reason for this lack of success.

### Need for Purposive Search

We do not want mere collectors of information, but men with a purpose in their inquiry, to synthesize teaching and hospital practice with private practice and explain unexpected and unsatisfactory results of treatment—the imprecision of such research may offend the sensibilities of the expert researcher, but to call it an "inquiry into" would be too reminiscent of a "Committee of Inquiry," which is the last thing wanted.

There must be, in the profession, many men of original mind thinking at times of the rightness of what they once doubted, now that they are free of the dominating influence of authority, wanting to prove it right or wrong, wondering whether their garden may not have grown too many useless plants for want of deeper digging when they could be thrown out, making room for something better, of more real value.

The younger men with unfaded aspirations and ideals will be the most likely to realize the need for more intensive inquiry as to the real value of their daily work, and among

these we may fairly look for original researchers. Their opportunities, if available, would be great—men with the mental capacity and aptitude who would, if they could, devote more time to so fascinating a study, but they have too often been prevented by the rush of work necessary to make a living. Some have, in spite of all, succeeded. Such a one was that great example Sir James Mackenzie, the general practitioner whose original clinical research was of value without measure. He is described by a biographer, Sir Thomas Lewis, as "an exact observer, with accurate deductions, a deep-rooted distrust of authoritative statement, originality of mind, determined in purpose, a real investigator"—a fine ideal for the humblest researcher.

### Appraisal of Failures and Fashions

Among the many subjects not only suitable but asking for investigation by the family doctor one may well put the results of treatment, especially the failures, as they are not so freely proclaimed, and it is necessary to examine them because if any sort of treatment is found to be useless it should be discarded, for so long as it is available or made use of, it prevents search for the really effective. The warning of a wrong path may save trouble or even disaster. It is the family doctor who has the most likely opportunities of observing the effectiveness or ineffectiveness of treatment, and it is the ultimate results that we want to know, because what seems to be early success may yet end in failure. With a new carburettor in your car you are not satisfied with a trial run on the level road: you want to test it up hill and under all sorts of conditions, its effect on fuel consumption and speed.

Inquiry into the results of therapeutic agents requires much care, and detachment from empirical, unproved, but fashionable agents. Under "treatment" should be included the important but as yet undetermined position of psychotherapy in adults, a field clearly for the observation and criticism of the family doctor, who can probably best estimate its ultimate value in actual practice. Treatment by the surgeon we assume may be readily appraised, probably so generally; but here again fashion or custom, or plausible advocacy, has sometimes overstated the case and prejudiced some such practice as the fixing of movable kidneys, excising feet of colon, for conditions which would not now be thought to require it, and, in a somewhat different category, the numerous cases of gastrectomy and gastro-enterostomy. These and other questions of surgical treatment, some too recent to-day for fair criticism, might with advantage to all be the subject of general practitioner inquiry as to not only ultimate failure but later unwanted and unexpected after-effects, or even harm.

### A Wide Field for Inquiry

This list of possible matters for inquiry as to their influence on the result of treatment is getting too long, so there can only be mentioned old age, heredity, economic and domestic and social conditions, housing, with all of which the general practitioner in particular is concerned, and the import of which, as affecting treatment, he has such a special opportunity of ascertaining. The doctor meditates on all these things, but has no time, if he has the incentive, to carry his meditations a stage further, though he probably compares the findings of actual practice with his textbooks, and attempts to draw conclusions as to the reality of "cause and effect."

These suggestions are merely tentative. Research to be of real use and effective will need to be more methodical. One can contemplate a doctor, when he has time, carrying in his pocket a small notebook, entitled "Clinical Research," in which he will note when he comes across a case of failed treatment: The case; the remedy, medical or surgical; how applied, under what conditions and surroundings; failure, immediate or remote; the reason; the lesson. For want of time this would be impossible under existing conditions of practice.

Although such research as here proposed must be individualistic, it would be better that it should be by groups of congenial workers, for there would have to be considerable numbers of separate observations, and the comparison of findings by the different members of a group would help to suggest errors and new points of observation. Eventually these might be not masses of records but collective opinions; and

other groups investigating the same subjects might, with the assistance of expert researchers, integrate their deductions as to causes and results, opinions, new outlooks, new ideas, and, better still if one could be found, the expert researcher might give advice as to the method of inquiry.

The suggested list of subjects for inquiry is merely intended as a reminding note to those who have been so long and are still striving so hard for success in treatment in spite of disheartening conditions, that still more striving will yet be demanded in their endeavour to find reality.

### The Day's Work, and Beyond

If even this simple form of research is to be undertaken it can only be done if the doctor has time to do all his work deliberately; anything less than this means that whatever his duties, whatever his pay, whatever system he works under, the public will not, cannot, be receiving the best possible medical service. If the public realized how unsatisfactory some treatment is from the doctor's point of view they would not remain so complacent and satisfied with what they are getting as they now are.

A general increase of research into the results of practice might increase the quality but not the quantity of the general practitioner's work. Some diversion from routine is wanted to help him to look beyond the day's work, which has been carried on under such serious difficulties, with little encouragement, often disillusion and disappointment. He wants something to encourage and help him to think originally, independent of fads and fashions, of patients and employers, some release from drudgery. Temporary relief comes to some by outside hobbies, but something within the sphere of his profession may add zest to his everyday round—may give a wider interest within his work for the better enjoyment of his professional life and for the benefit of his patients and of medicine.

The outcome of this should be of some interest or even value to specialists and consultants as well as other practitioners. It is a long view of what might be done, an idea that it is hoped others much more fitted may approve and help to develop.

### SMOKE CONTROL IN GREATER LONDON

Representatives of 67 boroughs and other municipal authorities, members of the Greater London Advisory Council for Smoke Abatement, met at the House of Commons on May 8 to consider the reduction of smoke in post-war London.

The conference was opened by the Minister of Health, who said that great areas of London would not look as they do if it were not for the smoke of the past and the present. He reminded the conference that the Government had not been inactive. Between 1919 and 1923 there was an improvement of about 50% in the deposits dropped on London. Then there was a stationary period and some deterioration, but between 1935 and 1939 there was again an improvement. He was very glad to find this revival of activity on the part of both that organization and the National Smoke Abatement Society and the realization of the fact that this was now the time to move. He hoped that their campaigns of education would be successful. He would be glad to do what he could in the field of research and in collaboration with the Ministry of Works and the right sort of standardization. In regard to post-war housing they had to face a limited supply of naturally smokeless fuels and a relatively small supply of carbonized fuel. There were also considerable difficulties now in regard to the better cleaning of coal. The direction in which one hoped for progress was in the manufacture of a really satisfactory improved grate which would burn raw coal more completely and would also burn smokeless fuels satisfactorily. There was no escaping the fact that the British public liked an open fire, and what they had to achieve was a fire which would be equally attractive, was economic, and would not need continuous watching. From all the expert opinion he could get it would not seem that research in this direction had yet reached finality. The departments concerned were very interested in the matter, and there was every reason why they should be because the loss of all kinds due to smoke was very great indeed. The building in which they were meeting had suffered terribly from atmospheric pollution.

The Minister continued that his Ministry, together with the Ministry of Works and the Ministry of Fuel and Power, were agreed that there should be efficient domestic heating appliances and practical methods of smoke prevention. During the summer the Ministry of Works would issue a housing manual in which the latest available knowledge on the subject would be given. He was anxious to do all he could to avoid smoke in the new suburbs and prevent the continuous spoiling of the centre of our cities.

### SCOTTISH SCIENTIFIC ADVISORY COMMITTEE

The terms of reference of the Scottish Scientific Advisory Committee have been revised and are now as follows: "To advise the Secretary of State on the application of the results of scientific research to public health administration and to promote medical investigations designed to assist the Secretary of State in the discharge of his responsibilities for the health services in Scotland."

Membership of the committee has been widened in the interests of medicine generally and includes: Sir John Orr (chairman), Prof. D. Cappell, Prof. F. A. E. Crew, Prof. E. W. H. Cruickshank, Prof. D. K. Henderson, Prof. J. Hendry, Sir A. S. M. Macgregor, Prof. T. J. Mackie, Prof. J. W. McNee, Prof. C. McNeil, and Prof. Noah Morris. Dr. I. N. Sutherland of the Department of Health for Scotland is medical secretary. Normally the appointment will be for four years, but to provide for rotation five of the members now appointed will retire after two years. The chairman of the Medical Advisory Committee (Sir John Fraser) and the secretary of the M.R.C. (Sir Edward Mellanby) are *ex-officio* members of the committee but are not subject to the rules of retirement.

One of the new committee's first tasks will be an investigation into the causes of infant deaths from infections. In making this announcement Mr. Tom Johnston recalled that the reports of the original committee, which was due to retire in 1940 but was kept in being because of the war, on the Emergency Bacteriology Service and the Blood Transfusion Service paved the way for setting up services that had worked smoothly and efficiently. The results of an investigation into the health and working experience of 1,000 Scottish men and women who had been boarded out of the Forces were incorporated in the Department of Health's booklet *Experiments in Social Medicine*, while an earlier report on maternal mortality (in 1935) formed the basis of the Scottish Maternity Services Act, 1937. It was likely, he said, that the subject of mental deficiency might be referred to the committee for inquiry and investigation later.

## Medico-Legal

### A PENSION FOR TUBERCULOSIS

Originally workmen's compensation was intended to be payable only when a workman suffered injury or death by accident but quite early in the history of the Acts the House of Lords held that anthrax was an accident causing injury. Lord Halsbury, Lord Chancellor, said: "When some affection of our physical frame is in any way induced by an accident we must be on our guard that we are not misled by medical phrases to alter the proper application of the phrase 'accident causing injury,' because the injury inflicted by accident sets up a condition of things which medical men describe as disease." The same principle was recently applied in construing another Act.

A policeman was discharged from the City of London Police Force for pulmonary tuberculosis, and applied for a special pension for life under the Police Pensions Act, 1921. This provides that every member of a police force incapacitated by infirmity of mind or body occasioned by an injury received in the execution of his duty without his own default shall be entitled to a pension. The police authority the Common Council, would not allow him a pension, but quarter sessions overruled it. The Council appealed to the Divisional Court submitting that tuberculosis was not an injury under the Act, and that there was no evidence that the policeman had contracted it in the execution of his duty. The court<sup>2</sup> unanimously found in his favour, and Mr. Justice Humphreys said he was not aware of any legal principle or canon of construction which should prevent tuberculosis from being described as an injury occasioning infirmity of body. When the courts disallow claims of this kind for workmen's compensation, the reason is not the absence of proved injury but the failure to identify any event which could, however loosely, be called an accident. Under the Police Pensions Act there is no need to prove an accident; the injury is sufficient, and the court were quite clear that the tuberculosis was an injury. On the question of fact, the learned judge admitted it would probably be impossible to establish by evidence the day, week, or even month during which the infection of the lung occurred. The court, however, was not required to decide the issue of fact, but merely to be satisfied that quarter sessions had had some evidence on which they could conclude that the injury had occurred in the execution of the man's

<sup>1</sup> *Brintons v. Turvey*, 1905, A.C. 230.

<sup>2</sup> *Garvin v. Police Authority for the City of London*, (1944) 1 All E.R. 375.

duty. Where it is shown that the conditions of service during the critical period were such as to cause unusual mental and bodily strain which, acting upon a frame ordinarily healthy but at the time enfeebled by long hours of duty, frequent wettings, and such hardships, rendered it more liable than usual to infection, the judge thought the injury might be described as the direct result of the duty and therefore suffered in its execution.

## Reports of Societies

### MILITARY ORTHOPAEDICS

Of special interest at the spring meeting of the British Orthopaedic Association, which was held at Leeds on May 12 and 13 under the presidency of Mr. St. J. D. BUNTON, were several short papers on orthopaedics in military centres.

#### Cartilage Operations and Rehabilitation

Major R. H. METCALFE, speaking on the indications for and results of cartilage operations, said he had studied two large series of cases in two consecutive years (1942, 1943) in the same military hospital. In the first year 600 knee-cartilage cases were seen in the out-patient department; 100 of these patients were admitted to the wards, and 60 of the 100 were operated upon. In the second year 800 cases were seen, 170 were admitted, and there were 100 operations. A follow-up showed that during the first year the average time off duty for those who were operated upon was nine weeks; their final grades were: A 60%, B 28%, C 8%, E 4%. The commonest cause of a bad result was abnormal antero-posterior mobility, which was not, in the majority of cases, the result of operation; other causes were osteochondritis and osteo-arthritis. The first year's results suggested that rehabilitation had been too vigorous and tended to arouse latent anxiety. Patients were more carefully selected for operation in 1943, and given a shorter period off duty and less vigorous rehabilitation. By getting the soldier back to his unit within the permitted period of three weeks before being "Y" listed the best results were obtained. This was possible in 20% of all the cases operated upon in 1943; these men were graded: A 81%, B 14%, C 5%, and none had been discharged. For the entire 1943 series the final grades were A 71.5%, B 20.5%, C 7%, E 1%.

#### Fractures of the Scaphoid

Major J. STEWART, U.S. Army Medical Corps, in a paper on fracture of the carpal scaphoid, said this fracture was often undiagnosed, and he emphasized the need for multiple radiographs on different occasions in doubtful cases. Difficulties were experienced in distinguishing new from old fractures and in estimating the nature of vascular changes. The end-results had been ascertained in 134 cases out of a series of 205 treated within 15 months; of these 134, 129 had been treated in plaster alone, of which 127 had full union and mobility, freedom from pain, full grip, and had returned to full duty. The procedure was immobilization in plaster-of-Paris, extending from the base of the thumb-nail, the proximal palmar crease, and the heads of the metacarpals behind to within one inch of the elbow-joint. The wrist was maintained in 10 to 15 degrees dorsiflexion, but with no lateral deviation. During the application of plaster the thumb and fingers were held as though grasping a football; this allowed full mobility of the fingers afterwards and practically normal activity for the hand. Recovery after the plaster was removed was shortened (nearly four weeks). The plaster was changed every three or four weeks, and progress checked by x rays, care being taken to prevent movement of the wrist and thumb during these procedures. Every sprain or injury in the region of the carpal scaphoid should be considered a fracture until proved otherwise. Solid bony union in an average of eleven weeks could be expected if there were early diagnosis, accurate reduction, and adequate immobilization for a sufficient period. Loss of Army man-power due to delay in union was directly attributable to failure to observe these principles. In fractures coming late for treatment the time of recovery was prolonged, but neither vacuolation nor sclerosis at the site of

fracture, provided the proximal fragment was viable, need be regarded as vitiating recovery by prolonged fixation.

#### March Fractures

Capt. E. WYNNE-JONES found that the incidence of march fracture of the metatarsal bones in Army recruits was 2.8%, and occurred towards the end of training in men generally of poor physique and posture with long narrow feet, and where there was mechanical overloading of the metatarsals. By a more careful gradation of route marches the incidence of these had been reduced to 0.91%. While immobilization in plaster gave satisfactory results, a simpler and more time-saving method was a metatarsal pad applied to the foot with adhesive strapping. Modified training (everything except roadwork, running, jumping, and obstacle-course work) was started immediately and continued until all tenderness had disappeared (average 21 days).

Two other papers dealt with operative techniques. Lieut.-Col. GLEN SPURLING of the U.S. Army Medical Corps described the use of finely drawn tantalum wire for nerve suture, and of tantalum foil as an enclosing sheath at the line of junction so as to prevent adhesions. This metal, besides being malleable and having tensile strength, was completely inert to living tissues. Capt. D. KILLORAN, U.S. Army Medical Corps, described a method of coagulum contact skin grafting similar to that reported by Sano of Philadelphia, but with modifications necessitated by lack of heparin. From oxalated blood, plasma and a leucocyte cream were prepared; the former is applied to recipient areas and the latter painted on to the deep surface of the graft. This procedure was adopted in battle casualties a few days after initial débridement and where there were no other means of closing a large skin defect. The limbs were then immobilized, but pressure dressings were not applied. Lieut.-Col. BRICKER thought there was some doubt as to how far such a coagulum glue could replace suture and pressure fixation of the graft; certainly it was a useful adjunct. He said that grafts should not be washed in saline before application, as such procedure removed natural adhesive.

#### Miscellaneous Papers

Prof. A. DURWOOD described his researches into the blood supply of nerves; these confirmed the importance of the longitudinally disposed intraneural vessels, which freely anastomosed and conveyed blood for long distances within nerves, even after division of the many small vasa nervorum which enter laterally. Discussing the characteristic histology of benign giant-celled synovioma of tendon sheaths Prof. M. J. STEWART said that the intracellular presence of haemosiderin or lipoids was merely a demonstration of phagocytosis by the polymorphous connective-tissue cells of which the tumour was composed. The presence of foam cells did not justify the description of certain of these tumours as "xanthomas"; in fact the "xanthic" reaction wherever seen was a local phagocytic response by connective-tissue cells to the chemical conditions of their surroundings. Dr. A. S. JOHNSTONE reviewed the work of Batson of Philadelphia on the vertebral venous system as a mechanism for the spread of metastases and his own investigations along the same lines. He said that while there was a freer connexion than was commonly recognized between the veins of the prostate and those of the vertebral column, and while the vertebral venous system might provide a means for some of the occasional spread from this and other organs, it by no means accounted for the spread of cancer by the classical means already accepted.

Dr. J. R. NUTTALL described the results of treatment of osteo-arthritis by deep x-ray therapy in 259 cases, 164 of which had been followed up. There had been no particular selection of cases for treatment. He found 17 patients who had had complete relief of pain three months after treatment ended, 90 had incomplete relief, and 57 received no benefit at all. His impression was that the best results were obtained in smaller joints. Mr. L. N. PYRAH reviewed a series of ten cases of generalized osteitis fibrosa, six of which had been admitted for spontaneous fracture. All of the patients were found to have parathyroid tumours, which were removed. In discussing blood calcium in such cases Mr. Pyrah emphasized that reliance was placed entirely upon blood calcium and phosphorus estimation,

except in one case in which calcium-balance experiments had been carried out. The blood calcium figure varied from 12.5 to 20 mg. per 100 c.cm. of blood, and the blood phosphorus in every case was low—usually 2 to 2.5 mg. The plasma phosphatase was raised in every case.

Mr. R. BROOMHEAD and his colleagues demonstrated a series of orthopaedic cases, including a group of people who had been operated upon for intractable metatarsalgia. At the operation the shaft and head of the metatarsal was denuded, and, after being osteotomized near its base, was rotated through 180 degrees.

The Indian Association for the Cultivation of Science recently founded a gold medal in memory of Dr. Binola Churn Law. In accordance with the terms of the endowment the medal "is to be bestowed on a person who, in the opinion of the committee of management, has made conspicuously important contributions to science, including medicine." The committee of management, under the chairmanship of the president of the association, Sir U. N. Brahmachari, decided in November last to make the first award of the medal to Sir Henry Dale, President of the Royal Society, by whom the medal has now been safely received. At a meeting of the Association for the Cultivation of Science on Feb. 4 Prof. A. V. Hill, biological secretary of the Royal Society, was awarded the Joykissen Mookerjee Gold Medal for 1944, and delivered an address.

The Easter Holiday course of the Ling Physical Education Association was attended by over 500 teachers, inspectors, and others, and the subjects discussed included health education in schools and clubs and social science in the physical training colleges, while there were lecture-demonstrations on rehabilitation of the injured, rehabilitation of children in occupied countries, and ante- and post-natal exercises. Mr. R. Watson-Jones, speaking on developments in orthopaedics, said that years ago it was thought sufficient to mend broken limbs; later re-education in muscular control was found equally necessary, and physiotherapy came into its own; now the psychological factor was considered of equal importance. He reminded his listeners of Plato's policy that there should be physicians for the body and physicians for the mind; they were indivisible. Lieut.-Col. J. W. T. Patterson described the Research Board for the Correlation of Medical Science and Physical Education, which, founded last year under the chairmanship of Brigadier Frank Howitt, was at work on a report on the co-ordination of the work of doctors and physical educationists in maternity and child welfare, education and recreation, the Services, and industry; it had also appointed a special scientific advisory committee, under the chairmanship of Sir Farquhar Buzzard, to collate and assess scientific research on the subject which had already been made and to initiate further research.

## Correspondence

### Infective Hepatitis

SIR,—In a recent account of infective hepatitis (Cameron, J. D. S., *Quart. J. Med.*, 1943, 12, 47, 193) the author, referring to myself, writes: "He still considers that there are two types, catarrhal and infective jaundice." That statement is incorrect. In the article of mine to which he refers (Cullinan, E. R., *Proc. roy. Soc. Med.*, 1939, 32, 933) I said I did not believe that there was convincing evidence that common infective jaundice, as seen in Britain, had two separate pathologies, and that if the two conditions did exist I regarded them as clinically indistinguishable from each other. Later experience in the Middle East and East Africa has strengthened and widened that belief. My reason for writing this letter is not to cavil at an obvious misprint—the author did not have the opportunity to read the proofs—but because occasional attempts to differentiate clinically what is now called infective hepatitis into two diseases are again causing confusion. For example, an article has appeared in the German press (Mancke, R., and Siede, W., *Münch. med. Wschr.*, Nov. 6, 1942, No. 45) entitled (translated) "The Differential Diagnosis of Catarrhal Jaundice and Epidemic Hepatitis." The authors consider that if all the symptoms are taken together these two diseases can be distinguished clinically from each other. Briefly, their distinction is as follows:

**Epidemic Hepatitis.**—Two-phasic disease. The first stage is a heavy general infection with fever lasting 4 to 6 days. During this

stage the liver is enlarged and very sensitive to pressure. The spleen may be enlarged. Urobilin is increased in the urine. Vomiting is a regular feature. Obstinate constipation is common. After about six days, often with great suddenness, jaundice appears. Fever settles by lysis. The patient feels much better. The liver may stay enlarged, though no longer tender.

**Catarrhal Jaundice.**—No clear-cut dual phase. May be a preliminary gastro-enteritis. No fever. Patient does not feel ill. Jaundice often the first abnormality noticed. Liver not spontaneously tender or painful. Vomiting very rare in the initial stage. Diarrhoea common.

I believe that this distinction is artificial and impossible to make. During an epidemic of infective hepatitis, although the first group of symptoms is the more common, not only does each group of symptoms appear in different patients but symptoms from both groups are often seen in the same patient. This is illustrated by the following brief case histories of eleven consecutive patients in an officers' mess in the Middle East. The number of officers in the mess was thirty-five. All the patients fell ill during a period of two months. It is not reasonably possible that they were suffering from different diseases.

(1) Loss of appetite. Felt slack. No vomiting. No fever. Jaundice on 7th day. Liver enlarged 3 fingerbreadths. Spleen not palpable.

(2) Loss of appetite. Felt slack. No fever. Jaundice on the 8th day. Liver enlarged 2 fbs. Spleen not palpable.

(3) Vomited one night. Continued to feel unwell, with nausea, for ten days. Then a "chill." General aches and pains and fever for two days. Loss of appetite, which persisted. Eight days later, jaundice. Liver and spleen not palpable.

(4) "Soaked to the skin." Fever for two days. Thought he had "flu." Poor appetite. Jaundice on 7th day. Liver enlarged 1 fb. Spleen just palpable.

(5) A "chill." Slight evening fever for four days. Loss of appetite after. Jaundice on 8th day.

(6) Lassitude. Complete loss of appetite. No fever. Vomited once on the 4th day. Jaundice on 9th day. Temp. 100°. Liver enlarged 2 fbs. Spleen not palpable.

(7) Dysentery. Six days later, loss of appetite. Five days after this, fever and enlargement of liver. Next day, jaundice.

(8) For four days thought to have malaria. Shivering. Slight fever. Unable to eat. Jaundice on 6th day. No enlargement or tenderness of liver. Spleen not felt.

(9) Malaise. Aching eyes. Slight fever for one day. Slight abdominal discomfort and loss of appetite persisted until 4th day, then jaundice. Liver enlarged 2 fbs. Spleen not felt.

(10) Felt ill. Shivery. Pain in back. Diarrhoea. Loss of appetite. Fever for a few days. Loss of appetite and feeling of illness persisted. Jaundice on 23rd day. Liver palpable 2 fbs. Spleen not felt.

(11) A "chill," with fever for two days. Following this, loss of appetite. Jaundice on 10th day. Liver just palpable. Spleen not felt.

Clearly no such clinical differentiation as suggested by Mancke and Siede could be made in these patients. The cause of infective hepatitis remains unknown. Recent work—epidemiological, clinical, and pathological—suggests a common disease process. Whether this will prove ultimately to be true remains to be seen, but any attempt at present to differentiate the disease by clinical data into different pathological processes is not only impossible but misleading.—I am, etc.,

E. R. CULLINAN, —  
Brigadier.

### Fracture of the Carpal Scaphoid

SIR,—In their paper (May 20, p. 685) Robertson and Wilkins rightly stress the importance of continuous immobilization in the treatment of recent fractures of the carpal scaphoid—a well-established principle in the treatment of all recent fractures—and their end-results in old-standing fractures of the carpal scaphoid show, as they state, the lamentable results that may follow a missed diagnosis and/or inadequate treatment. Of their 12 cases of "established non-union which had no other treatment than prolonged immobilization [many months] the men were discharged to light duty," and but for their special value to the Service would probably have been invalided as unfit. "Most of these cases showed some degree of osteoarthritis and disability of the wrist." Of the 12 cases which received operative treatment (3 bone graft, 2 excision of proximal fragment, 7 drilling) only 4 returned to duty. Are these the best results obtainable in old-standing cases? The authors will surely admit that these are very disappointing results.

In my experience better results can be got in old-standing cases by excision of the whole scaphoid, as the following cases show.

1. A joiner aged 24 fractured his scaphoid in 1915. In Nov., 1922, he was seen by me and complained of pain in the wrist after much hammering or planing. X-ray examination showed an ununited fracture of the scaphoid. On Dec. 6, 1922, I excised both fragments. He returned to work in six weeks and has had no trouble since.

2. A locomotive fireman aged 26 had an ununited fracture of the scaphoid of 7 or 8 years' duration. He had pain on jarring of the wrist when shovelling coal. Complete excision of the scaphoid was performed on Jan. 6, 1924. He returned to full work and has had no complaint since.

3. A tram conductor aged 32 fractured his right scaphoid on Aug. 28, 1927. He was treated in a "cock-up splint" for seven days. On Sept. 23, 1928, x-ray examination showed ununited fracture of the scaphoid. This man complained of pain in the wrist when punching tram tickets: this entailed constant use of the right thumb. On Sept. 26, 1928, the whole right scaphoid was removed. He returned to duty and has had no complaint since.

These three cases had been treated as sprain of the wrist and no x-ray examination had been done. All showed osteoarthritis and "cysts" in the fractured scaphoids. Two of these excised scaphoids were sent to the late D. M. Greig, and are now in the surgical museum of the Royal College of Surgeons, Edinburgh. The following characteristic remarks from Greig's letter acknowledging receipt of the specimens seem to me worth quoting: "Isn't the pain that these people suffer from not rather related to the ligaments meeting the strains at a disadvantage than to actual compression each time of the injured bone? I agree with you that excision is the proper treatment [for persistent non-union]. Rest may be good in the early stage, but not later, and I don't think at any time massage, electrical treatment, and such eclectic rot is of the least use. It may please the patient and gratify the radiotherapist, but it has no place in practical surgery."

In conclusion I suggest that Robertson and Wilkins (and other surgeons) might consider removal of both fragments in cases of old-standing non-union of the carpal scaphoid. In the three cases quoted there was complete relief from pain and no appreciable loss in strength or function of the wrist.—I am, etc.,

Dundee.

### Aerial Transmission of Virus Infections

SIR.—I cannot see why there should be the least hesitation in accepting the aerial transmission of smallpox, and for that matter that of other infective diseases. Botanists tell us that they readily collect, on plates smeared with glycerin exposed on high buildings and on aeroplanes, abundant pollen grains and the spores of fungi. These objects have no flight mechanisms and must be infinitely heavier and bulkier than viruses; and, as those familiar with the effects of A.A. gunfire will be aware, what goes up must also come down. To my mind the wonder is that these viruses are not disseminated much further than clinical experience has so far demonstrated. The accurate bacteriological proof may not be accomplished for some time, though the recent demonstration of the viability and transmission in the form of dust within a building, of streptococci and other micro-organisms may be a start in the right direction; though, where the air currents caused by sweeping and dusting are to be compared with the winds of heaven outside buildings, the areas of dissemination involved will be proportionately greater.—I am, etc.,

Witley.

J. G. C. SPENCER.

### Nutritional Oedema in a Vegetarian

SIR.—In his comment (May 20, p. 699) upon my article Dr. D. G. McIntosh probably has in mind the condition of acute "beriberi heart," which is associated with gross oedema and often terminates in sudden death from cardiac failure. This type of beriberi may be associated with nutritional oedema, but in my case the ordinary signs of cardiac failure were absent: there was no radiological or clinical evidence of cardiac enlargement, no venous congestion, and the blood-pressure readings were normal. There was no cyanosis, and the dyspnoea and slight tachycardia were not more than could be explained by the pleural effusions. Furthermore, there was

evidence of polyneuritis, which in some degree is always present in the cardiac type of beriberi. It is unfortunate that more detailed investigations of the circulatory efficiency were not done, such as an electrocardiogram, circulation rate, and blood volume, but these are hardly necessary in order to diagnose congestive failure. It is highly improbable that any serious cardiac lesion was present, as the infusion of several pints of plasma produced no cardiac embarrassment. It would have been dangerous to overload a failing circulation in this way, and the possibility was considered before giving the plasma.

Dr. McIntosh's remarks are apt, however, in that similar cases may be found in occupied Europe, and they may be complicated by gross vitamin deficiencies in addition to the simple hypoproteinaemia. In such cases plasma transfusion as a rapid method of restoration of the blood protein should be avoided owing to the risk of overloading the circulation.—I am, etc.,

J. MACDONALD HOLMES.

### Neurotic Battle Casualties

SIR.—Previous communications from this unit have reported the value of front-line sedation, sleep treatment, emotional abreaction, and modified insulin therapy in the rehabilitation of neurotic battle casualties. On the invasion of Europe more of these casualties are bound to occur. Sedation, insulin, and emotional abreaction deal with different aspects of the neurotic battle casualty. Hitherto the clinical picture has often required the consecutive use of all these methods to combat the tension, irritability, fatigue, exhaustion, loss of weight, and amnesias, to mention some of the features of such cases. During the past year I have found that a combined technique of continuous sleep and modified insulin was safe and often a therapeutic advantage. One could treat the patient in a comprehensive way promptly and with a minimum stay in hospital. In outline, insulin is given at 7 a.m., 10 up to 50 or 60 units according to individual tolerance as described by Sargent, while sleep is maintained with the short-acting barbiturate sodium amylal for 18 to 21 hours daily. During the insulin period sleep is kept relatively light, not more than gr. 6 of sodium amylal being given in this time. If need be, emotional abreaction of traumatic incidents is conducted in the afternoon, since the patient is then in the same drowsy state as occurs with intravenous barbiturates given specifically for this purpose. The essentials are that the staff be familiar with states of hypoglycaemia and sleep, that the food and fluid intake be kept at a high level, that 2 oz. glucose be given at teatime, and glucose kept at hand for oral or intravenous use if required—though in practice the need is rare. Treatment can be maintained for 14 days or longer, but where more than 4 to 5 days is necessary the sedative must be very slowly reduced to prevent a barbiturate withdrawal fit occurring, especially if insulin is continued after the full sleep course is terminated.

This technique is reported since it may prove useful for those who have to deal with acute battle casualties which have not responded to front-line sedation.—I am, etc.,

Sutton Emergency Hospital

D. E. SANDS.

### Mental Disturbance after Atebrin

SIR.—Dr. Gerrard, in his letter on the treatment of malaria (Feb. 5, p. 196), states that he encountered none of the alarming complications recorded by other writers on atebrin therapy in his investigations into this line of treatment in Hong Kong.

During the period 1939-41 I saw three cases of the so-called "atebrin psychosis" in Hong Kong. Two of these patients were young Chinese and the third was a middle-aged Dutchman who had needed periods of treatment in mental hospitals on several previous occasions. All three patients had been given 0.3 g. of atebrin intramuscularly for a fever presumed to be malaria, and all developed mental disturbance shortly after administration of the drug. The picture they presented was that of an acutely oncoming confusional state; temporal and spatial disorientation, hyperkinesia, and persistent insomnia being the outstanding features. The Dutchman was so violent that he had to be admitted to a mental hospital for 48 hours. Recovery was complete and rapid in all three cases, and seems

<sup>1</sup> *Lancet*, 1940, 7, 1; 1941, 1, 107; 2, 212; *British Medical Journal*, 1942, 2, 573; *War Medicine*, 1943, 4, 577.

to be assured once the normal sleep rhythm is restored. Similar disturbances after the use of atebirin have been reported by many other observers, particularly those working in the Far East.

In view of the fact that atebirin now bids fair to replace quinine in the treatment of malaria (for the time only, let us hope) it should be emphasized that the Eastern races and those patients with a past history of mental instability may develop acute mental disturbance if given atebirin by the intramuscular route.—I am, etc.,

Famagusta, Cyprus.

PAUL WILKINSON.

### X-ray Examination of Service Recruits

SIR,—Dr. Bernard Leggett (May 20, p. 700), in referring to the gastro-intestinal x-ray examinations of Service recruits for the Ministry of Labour, questions "the value of those one or two film examinations done without prior preparation at the instance of the Ministry of Labour with negative results." I would agree with him if this were generally the case, but, having x-rayed Service recruits for the Ministry for four years, it is only fair to say that my experience is totally different. Neither the Ministry nor their medical boards have ever suggested the number of films I should use in any examination, nor have I come across an instance of a medical board failing to give a recruit proper instructions for preparation before the examination. If an inadequate number of films is used, as Dr. Leggett states, and the medical boards are not informed as to the preparation required it is the fault of the individual radiologist and not of the Ministry of Labour.—I am, etc.,

London, W.1.

H. GRAHAM HODGSON.

### Operation for Umbilical Hernia in Children

SIR,—It was with keen interest that I found the question of injection treatment or operation for hernia taken up by Mr. Bennett-Jones in the *Journal* of Jan. 15 (p. 78) and applied to umbilical hernia in children. While most of his statements coincide with my own ideas and experience in this matter, I cannot feel tempted by the statistics given either to advocate or to use the injection treatment in such cases myself. For children who do not show a tendency to cure otherwise I rather adopt the attitude for umbilical hernia which Mr. Bennett-Jones himself pronounces with regard to inguinal hernia. Here it certainly holds good even more that "operative treatment is so safe, with recurrence and sepsis almost unknown." It is my own idea, as much as it is Mr. Bennett-Jones's, that admission to hospital should be avoided whenever possible, and to his arguments of shortage of beds and the danger of infection I should like to add the fact, stressed and proved by Herzfeld of Edinburgh, that children never get on so well in an institution the first time after admission.

The conclusion I drew from the facts mentioned was to look upon the operation on children without admission to hospital as the method of choice. That was recommended first by Stiles, I think, and observations of large numbers of such operations without complications and with perfectly satisfactory results have been published by Herzfeld of Edinburgh and MacLennan of Glasgow. According to Michailoff it seems that in Russia, too, operating on children as out-patients was nothing unusual. Encouraged by these reports and by Schwarzmann, my senior surgeon in Vienna (now in New York), I adopted this treatment many years ago, and in 1935 I published a report based on our experience covering 10 years. Space does not permit me to go into details of technique and results here, but I should like to emphasize that the procedure is so simple and the results are so perfect that I felt justified, even in my present practice without being attached to a hospital, to do an occasional umbilical hernia in the patient's home, using the dining table (Morrison shelter) as an operating table with the district nurse assisting. There was never the slightest trouble; the results were perfect, and mother and child as happy as can be. It seems to me, therefore, that the operation for umbilical hernia in children without admission to hospital might be taken up more widely than seems to be done at present.—I am, etc.,

Gillingham, Kent.

K. F. POLLACZEK.

### Poisoning the Endocrine Glands

SIR,—Recent work on the influences of thiouracil on the thyroid and of alloxan on the pancreatic islets, which, as set out in your leader (April 29, p. 595), represents the action of two substances poisoning selectively the endocrine glands, recalls earlier work on the action of thallium salts, which have undoubtedly a specific poisonous influence on the endocrine system. The use of thallium as a remedy against overgrowth of hair has been more or less abandoned owing to its toxicity, which has even led to the death of a number of patients. The experimental work (which seems to have been almost forgotten and which in the light of modern endocrinology is far from being complete) suggests, however, that thallium has either a specific pluriglandular action or a selective action on the anterior pituitary lobe, with subsequent cessation of function and degeneration mainly of the thyroid gland and of the gonads. The cytological changes of the Golgi apparatus and of the mitochondria in the thyroid cells after administration of thallium acetate are those found when there is diminished thyroid secretion. The cells themselves become flattened, the colloid stains acidophil, and the basal metabolic rate diminished (Ma, Wen-Chao, and Jui-Wu, *Proc. Soc. exp. Biol.*, N.Y., 1929, 27, 249). In rodents oestrus ceases completely, and returns one to eight weeks after discontinuation of thallium administration. No other known poison is able to produce such an action, nor do deep x rays have an equally prompt effect. The histological appearances of the ovaries of these animals are normal. That the inhibition of the oestrus is not due to general poisoning or to lack of ovarian reactivity but to a cessation of oestrogen production; probably through inhibition of gonadotrophic stimulation, is shown by the fact that oestrogen or gonadotrophins are able to produce an oestrogen response in animals under thallium treatment (Buschke, B. Zondeck, and Berman, *Klin. Wschr.*, 1927, 15, 683). In young rats retardation of growth, complete atrophy of the testicles, lack of sex desire, loss of hair, and cataract formation occur. Alopecia can be produced in youngsters by feeding thallium to the mother.

There seems to be no doubt that thallium is a specific endocrine poison which merits to be studied again from this point of view as to its functional and anatomical effects on the endocrine glands, especially on the pituitary, and that it is likely to be of therapeutic value once the mechanism of its action has been clarified and a suitable dosage established.—I am, etc.,

London, W.1.

H. UCKO.

### Service Medicine

SIR,—Recent correspondence on this subject has caused me to look up the extracts from the letter of an anonymous writer which appeared in the *Journal* of April 1. This unhappy correspondent appears to have missed all the joy and spirit of comradeship in what most of us regard as the most exciting period of our lives. Perhaps it would help him if he were to learn of the experience of one who was, until recently, a specialist in the R.A.M.C. and also a patient who owes much to the skill and care of the specialists in that corps.

When suffering from an obscure illness I was examined by five specialists in different branches of medicine. Each of these officers is a man of nation-wide reputation, and each one impressed me with his enthusiasm for his work and the sympathetic interest he took in my case. As a result of this investigation a correct diagnosis was made in a very short time, correct treatment was instituted, and, after a slow convalescence I was restored to health. Each of these gentlemen had to fill up a form and write a report about my case, but since these forms when taken together helped to save my life or at least save me from years of ill-health I may be pardoned for regarding them as valuable documents. In addition, these forms were of importance to me when it came to assessing my pension.

Like other correspondents I have been a consultant and a member of the staff of a teaching hospital for several years and, like them, I agree that the soldier gets better treatment than does the civilian, even in peacetime.

Except for about four months, when, by reason of ill-health, I was given a light job, I found that I had rather more work to do in the Army than I had in civilian life. I found more cases of special clinical interest to me in a military hospital than I have ever found in the same period in my civilian hospital. The team spirit is more in evidence in the Army than elsewhere, and it is a great help to a physician to be able to have the opinion of any other specialist without wondering whether it is fair to the patient to incur the additional expense. My civilian colleagues are invariably helpful and co-operative, but it is necessary to remember that the time they give to the hospital patient is time taken from their private and remunerative work.

There are some misfits in the Army Medical Service, and it is not always possible at the time to see the reasons for the wisdom of some of the orders we receive. Nevertheless I am convinced that the A.M.S. is directed efficiently, and the work of that department is characterized by wisdom, foresight, and, so far as individual officers are concerned, with great personal kindness. I am afraid the views of the anonymous correspondent are held by many, and the experience of the medical services in the present war is necessary, therefore, that every effort be made to remove facts before the medical profession. I am, etc.

Belfast.

T. A. ...  
Major

SIR.—With regard to the correspondence on this subject I am struck by the high Service ranks of those who write to support the Service point of view—brigade major, squadron leader. I have no doubt what the writer's point of view is, but I am sure that the letter giving rise to this correspondence is also quite good. In the Service so many of the patients are on the individual's ability to fit in, and many cannot get used to compulsory formation and the doctors keep no written records at all, and have no supervision—possibly because the fear it. We have men of the calibre of J. J. Conroy, under whose supervision I studied medicine some twenty-two years ago.

The main purpose of this letter, however, is to notice the point of view of Service patients. I have, from my own experience, and that of almost all my colleagues, whom I have spoken, that our patients in the Service are like the medical arrangements and do not trust the Service doctor. Again and again I have had personnel from the Services come to me on leave to unburden themselves and worry they feel they cannot take to the Service doctor. They know they will get excellent treatment if they leave the Service and go into hospital, but they cannot obtain it in comfort and support they look for from their doctors in the Service. This even applies to men who have been decorated for bravery on the field. They seem to think the unit doctor is too busy and has no personal interest in them.—I am, etc.

Bristol.

J. J. FULLER

### Expectation of Life in Urinary Tuberculosis

SIR.—To corroborate the memorandum by the late Mr. Henry Fenwick (May 6, p. 621) and the letter of Mr. Victor Barnard (May 20, p. 700) on occasional cases of longevities after infection I can record one case that was even more to the point. Early in 1907 a lady aged 53 had considerable distress of micturition. I found that she had tubercle bacilli in purulent urine and an enlarged right kidney. Mr. Hurry Fenwick made a cystoscopic examination and diagnosed the illness as one of tuberculous right kidney. He advised me to try tuberculin injections. This I did in small doses, and combined them with prolonged rest and a sensible fresh-air treatment. Later on Sir Almroth Wright saw her and agreed with the diagnosis and treatment. The urine gradually cleared of pus and tubercle bacilli; she was under treatment for three years. The right kidney remained large and micturition was at times frequent. This woman fully regained her good health and activity, there were no relapses; she died in January, 1940, aged 80, of senile aortic disease. Her infection had been almost certainly acquired from a "bronchitic" cook, whom I found to be expectorating

tubercle bacilli in abundance. These rare cases of great natural resistance have, of course, no bearing on the modern surgical treatment of tuberculosis of the kidney.—I am, etc.,

Hastings

HARRY GABB.

### Ophthalmologist and Optician

SIR.—In a previous letter (May 6, p. 635) on the question of ophthalmic surgeon and optician I expressed a doubt as to whether the sight-testing opticians would co-operate as medical auxiliaries in a national eye scheme. The letter which you have published from Mr. W. B. Barker (May 20, p. 702) shows this to be the case, but it also proves a far more important point. By his statement that for an optician to undergo medical training would be "as wasteful and unnecessary a basis for optical practice as it would be for dental practice" he tells us that he has no conception at all of the organ with which he is dealing. An aching tooth or dental sepsis is essentially a local condition, but an aching eye or a tired eye may be a danger signal of general disease, and these signs may be important.

The eyes are the windows of the body, and the very earliest signs and symptoms of diseases of the nervous system, the circulatory system, etc., may present themselves in the eye. If the patient with papilloedema or diplopia is treated with spectacles or orthoptics the presence of an intracranial lesion may be unsuspected until it is too late. The neuro-ophthalmologist, aided by radiology and electro-encephalography, can detect and remove an intracranial neoplasm if he gets it in time, and it must be remembered that intracranial tumours are not rare but are only second in incidence to the uterine neoplasms. A neoplasm may develop in the eye itself at an early age and failure to recognize it may cost the patient his life. We have all seen, far too often, the patients with primary glaucomas who are treated with spectacles until but one small portion of one visual field remains. It will be seen, therefore, that the eyes of which we have only two, and the teeth, of which we have 32, can in no way be compared, and yet no dental surgeon would refer to his course in anatomy and general pathology as a waste of time. Finally, dentures prove a very efficient substitute for our teeth, but an artificial eye is useless as an organ of sight.—I am, etc.

LESLIE HARTLEY.

SIR.—Possessing no knowledge of optics practitioners cannot decide whether sight-testing is the concern of medicine or can be undertaken by opticians. In forming a judgment it is essential to recognize that this testing is merely a measurement of the eye, and, except that the technique is more involved, is akin to other bodily measurements. Where it differs is that the symptoms of an eye defect may simulate disease, and an eye must be pronounced healthy before glasses are given. This contention the optician has accepted for at least two decades, and he maintains that his training enables him to fulfil his obligation in that it comprises the same methods of investigation that oculists universally use.

The means of determining health, applicable to every organ, constitute a study of symptoms, the investigation of functions, and, in the eye, an external and internal inspection. In investigating function the optician not only considers direct vision, but the fields for colour and white are taken when these procedures are indicated. As the luminous ophthalmoscope makes the interior of the eye almost as visible as is a face, the overlooking of a lesion is inexcusable.

But for a service to be efficient it must be more than competent; it must be readily available and at a cost that is not disproportionate to the service that is rendered. To recruit "sight-testers" solely from medical men would so curtail facilities that, rather than suffer the inconvenience and expense, patients would gradually resort to selecting their glasses themselves at a general store as some do to-day. Further, a medical training is too valuable to be wasted on measuring, and many, like myself, are convinced that not only is it in the interest of medicine to delegate sight-testing but it is also to the benefit of the community that the hand which fits the frame should be responsible for prescribing the lens.—I am, etc.,

London, W.1

JAMES FORREST.

### Work of Women Doctors: A Survey

SIR,—The Medical Women's Federation considers it important that accurate and up-to-date information concerning the work of medical women should be obtained—e.g., the number who give up medical work temporarily or permanently after qualification, etc. The Federation is therefore undertaking a survey of the work of women doctors and a questionnaire is being sent to every woman by a representative from each medical school in Great Britain and Northern Ireland which admits women students now or has done so in the past.

May I, through your columns, urge all medical women, whether engaged in medical work or not, to complete and return the questionnaire without delay? It is possible that some may not receive the questionnaire owing to change of name or address. Will they please apply to the office of the Federation (73, Bourne Way, Hayes, Bromley, Kent) asking to be put in touch with their medical school representative in order that a questionnaire can be sent to them?

In the cases of graduates from the London (R.F.H.) School of Medicine for Women, the inquiry is being conducted by Prof. Lucas Keene. As regards all other medical schools the dean's office is not concerned in this matter and has no information to give about it.

This request does not apply to women who qualified from University College Hospital Medical School (University of London) or from Birmingham Medical School, as the information from graduates in these schools has already been obtained. —I am, etc.,

JANET K. AITKEN,  
President, Medical Women's Federation.

## Obituary

By the death in his 91st year of GEORGE HOLLIES of Wellington, Salop, the profession in Shropshire has lost its oldest and the B.M.A. one of its oldest members. Dr. Hollies began his professional life in a way not uncommon in his young days but almost unknown at the present time by becoming a pupil to a well-known practitioner in the town of Halesowen, Worcestershire. After a period of pupillage, when he was contemplating entry to a medical school, his father died and left him practically stranded. But this did not deter him; he proceeded to earn his living by assistantships, not very well paid in those days, and saved money for his fees. His last assistantship was in Cambridge, and during this period he entered as an undergraduate, and eventually took the B.A. degree. He completed his curriculum at the London Hospital and in Birmingham, and qualified as L.R.C.P., L.R.C.S.Ed., and subsequently graduated M.B., B.Ch. of Trinity College, Dublin. Offered a partnership by the late Dr. Steedman of Wellington, Salop, he settled down in that town, and for many years was the leading practitioner there, gaining the respect of all and the affection of large numbers. He was a member of the B.M.A. for many years, a member of the Shropshire and Mid-Wales Branch Council, and president of the Branch. He concerned himself with all the public activities of his town and county. He was a J.P., the first chairman of the urban district council, an alderman of the county, and chairman of its public health committee. For 40 years he was a volunteer or territorial medical officer, attaining the rank of lieutenant-col. R.A.M.C.(T.) attached to the Cheshire Brigade R.F.A. In the last war he was the oldest medical officer in the Western Command, and served as S.M.O. Divisional Mounted Troops, Welsh Division, until he was invalided out in 1916. His wife died about 20 years ago, and he leaves no direct survivor, but several of his nephews are in the medical profession.

Dr. ARTHUR HENRY HOWARD HOWARD, who died at Millbrook, Plymouth, on April 20, aged 63, had practised there for a considerable time. He took the M.R.C.S., L.R.C.P. in 1909 after professional training at Charing Cross Hospital, and served there as house-surgeon. He was then medical officer for three years to the Children's Hospital at Much Hadham, Herts. During the last war he held a commission in the R.A.M.C. and was attached to No. 32 British General Hospital, Amara, after which he became officer in command of the 323rd Field Ambulance, and returned to this country to take charge of the ear department of the Clipstone Military Hospital, Notts. His first association with Sheffield, where he practised in partner-

ship for some years, had been as casualty officer to the Royal Infirmary and anaesthetist to the Royal Hospital. At Plymouth he was medical officer and public vaccinator for St. Germans, and surgeon to the police and the post office.

The passing of Dr. ARTHUR STANLEY PARKINSON on May 2 has caused widespread regret among his patients, colleagues, and friends. Born at Bradford in 1877, he came of a family who had practised medicine for several generations. He was educated at the Leeds Medical School and subsequently pursued postgraduate studies in Paris, obtaining the M.B., Ch.B.Vict. in 1900, the M.D.Leds in 1905, and the D.P.H. in 1906. The appointments he had held were: house-surgeon to the General Infirmary at Leeds; resident physician to the Worcester Consumptive Sanatorium, Knightwick; and resident medical officer to the Consumptive Sanatorium, Gateforth. His publications included several articles on tuberculosis, and his membership of the British Medical Association extended over many years. From 1908 to 1931, except for service in the R.A.M.C. for which he volunteered during the last war, he resided in Wavertree, Liverpool, where he established a large practice. After several years in Hastings, he eventually returned to the North-West and lived at West Kirby. Though he had decided to retire, with the outbreak of war and consequent shortage of medical practitioners he energetically recommenced practice and also undertook valuable work in the examination of recruits. Dr. Parkinson represented the finest type of general practitioner, possessing marked ability and always keeping abreast of modern advances. Ever cheerful, it is impossible to speak too highly of his kindness and devotion to his patients. His passing is indeed a great loss.—H. H. S.

Dr. WALDEMAR BARTHOLOM SOMMERS died on May 9, at Redhill, Surrey, after a long and patiently borne illness. He was born in New Zealand, coming to Edinburgh to study medicine in 1902, where he graduated M.B., Ch.B. with 2nd class honours in 1908. After a year as house-physician to Prof. Greenfield he was appointed medical officer to the Burmah Oil Company, and he carried on his work at Syriam, the oil refinery. While on leave in 1914 he took the F.R.C.S.Ed. At the end of his contract in 1925 he retired to Redhill. J. C. L. writes: "I was a fellow student of Bart Sommers and then joined him in Burma. Since coming back I have kept in the closest touch with him and have seen the wonderful philosophy and fortitude with which he bore his very distressing illness for nearly five years. He started medicine rather later than the majority of students, and to those of us who were privileged to become his friends this fortitude would have been expected of him. He was always quiet and rather reserved and did not make friends easily, but to those with whom he did he was always helpful in advice, both professional and social, to those younger than himself. He was a very sound physician and very modest with it all, and he earned much gratitude and praise both from the officials and from the natives with whom he came in contact during his all-too-short professional life. He was never particularly robust, so did not carry on any activities after his retirement from Burma. He leaves a widow, to whom all who knew him will extend the deepest sympathy.

Dr. CLAUDE GOULDESBOURGH, who died at Calstock, Cornwall, on May 12, aged 63, had practised for many years as a radiologist in London. He was educated at Rugby and Christ Church, Oxford, and studied medicine at St. Thomas's Hospital, taking the M.A., B.M., B.Ch. degrees in 1909, and was then casualty officer at St. Thomas's and house-physician at Addenbrooke's Hospital, Cambridge. Soon afterwards he began to specialize in radiology, and by 1914 had gained considerable experience as assistant superintendent of the x-ray department at St. Thomas's and M.O. in charge of the same department at the Royal Chest Hospital. In August, 1914, he went to France with the R.A.M.C.(T.), and became senior consulting radiologist to the B.E.F. In 1915 he returned to this country as consulting radiologist to the Empire Hospital for Officers, and wrote on military radiography in English hospitals in France during the first nine months of the war for the *Journal of the R.A.M.C.* Other hospitals with which Dr. Goulesbrough served as radiologist were the Royal Northern Hospital, the Royal Westminster Ophthalmic Hospital, the Bethlem Royal Hospital, and St. Mark's Hospital, City Road.

Dr. HELEN STANLEY FAIRLEY was born in the Pas-de-Calais in 1875. She was a daughter of Major Richard Ireland Stanley and cousin of Sir William De Courcy Wheeler, a former president of the Royal College of Surgeons of Ireland. She spent a great part of her childhood with the Wheeler family and began her medical career at the Edinburgh College for Women in 1892, being one of the pioneer women in the profession. During this period she showed exceptional ability and qualified L.R.C.P.,

The second reading of the Rural Water Supplies and Sewerage Bill was moved on May 18 by Mr. WILLIAMS. He said the object of the Bill was to stimulate the making of plans in readiness for a sustained attack on the problem of the 30% of the inhabitants of rural England and Wales who were beyond the reach of adequate, wholesome supplies of water in pipes. The Bill proposed assistance to the extension of sewerage. It would guarantee that the Government would help rural authorities which, in planning extension of piped water and sewerage, would be faced with costs beyond what ratepayers and com-

sumers could reasonably bear. For England and Wales £15,000,000 and for Scotland £6,000,000 were proposed as grants-in-aid. A power to the Minister to compel amalgamation and bulk supply of water from one authority to another would be included in major legislation to be introduced later. The persons affected by this Bill numbered 2,000,000 out of 40,000,000, and the call on water reserves was not relatively heavy.

Mr. TOM JOHNSTON said the purpose was to provide in Scotland wholesome water in pipes to every rural locality where there were houses or schools and to take the pipes to where those houses or schools could be connected at reasonable cost.

The Bill was read a second time.

### Milk Supplies: New Central Control

Mr. ROBERT HUDSON moved on May 19 the second reading of the Milk and Dairies Bill. He said that consumption of liquid milk had gone up from 866,000,000 gallons yearly before the war to 1,185,000,000 gallons yearly. Supplies were insufficient and the Ministry of Food assumed that existing priority consumption by school-children and nursing and expectant mothers would continue after the war as part of the permanent social services. The Ministry of Food thought an additional 350,000,000 gallons of fresh milk per annum would be required before rationing could be abolished. Mr. Hudson hoped this would be accomplished. The aim must be not only milk in greater quantities but milk in which the public and the medical profession would have complete faith. This Bill was a necessary step to achieve that aim. Every dairy herd would, in future, be inspected by a qualified "vet" at least once a year. There were not enough "vets," and the provision for the training of more was under consideration. Steps for the control of disease had been extended. Mastitis, abortion, sterility, and Johne's disease were being dealt with by a scheme which had help from his Department. There had been an increase in the number of calves vaccinated against contagious abortion. He hoped soon to introduce a voluntary scheme which would enable the "vet" to carry out vaccination of the calves while he was at the farm. The Attested Herds Scheme against tuberculosis was making rapid progress before the war, but had to be suspended. He proposed shortly to reopen admission to that scheme. This would apply to both farmers selling their milk and farmers rearing stock. He hoped thus to build up whole areas free from tuberculosis from which dairy herds could be replenished with cattle free from the disease. In addition, the Ministry was pressing on with a national milk testing and advisory service. Of supplies to large depots, over 92% was now regularly tested; of producer-wholesalers' milk over 88%; and of producer-retailers 22%. The result was that the keeping quality of the nation's milk had been improved in the last two years. The Bill proposed to transfer to the Ministry functions which the local authorities had not always carried out. These were the inspection of premises, of equipment, and of methods of milk production. The powers had been entrusted to local authorities in 1926, when there was no State veterinary service and when milk supplies were drawn from the surrounding country; now supplies came to great cities for the most part from distant regions. Local authorities in the great consuming areas had no control over the conditions of their milk supplies. To carry out the provisions of the Bill he would have to increase his veterinary staff and also to recruit non-veterinary staff, men and women, with the qualifications of sanitary inspectors, milk inspectors, and so forth. He and the Ministry of Health would be jointly responsible for making regulations. The local authority would continue to be responsible for keeping a check on the cleanliness and purity of milk sold in its area.

Mr. TURTON moved to defer legislation until a Royal Commission had been appointed and had reported. Mr. CHARLES WHITE complained that tuberculin-tested milk was ordered to be mixed with milk of an inferior quality. Sir WILLIAM WAYLAND said the sanitary inspector was the proper man to examine the condition of a cowhouse. The veterinary inspector would not do that. It was not his trade. MRS. TATE contended that inspection of churns would still be the duty of the local authority. Mr. HUDSON remarked that Mr. Willink and he would make regulations in order that the churns would be properly inspected, which they were not at present.

### NO MENTION OF SAFEGUARDS

Sir GEORGE ELLISTON said conveyance of disease through milk went on year by year, and the almost unanimous view of the medical profession had long been that the only real protection for many years to come must be by heat treatment of milk supplies. That view had been adopted in Canada and the United States, yet the House of Commons discussed this Bill without mention of the available safeguards against diseases

caused by milk. It would be 40 or 50 years before the dairy herds of this country could be regarded as safe. It was regrettable that the Minister of Health should abdicate his powers over milk supplies. Power to make regulations should be retained by the Ministry of Health so long as any designated milk was allowed to be sold unpasteurized. Accredited milk had often been found to contain a higher percentage of tuberculous infection than raw unaccredited milk. That was the experience of the L.C.C. over five or six years.

Miss HORSBROUGH said all Members were dissatisfied with the present standard of the farms and with the lack of cleanliness of milk off the farms. The Government asked for a joint effort from the local authorities and the Ministry. Local authorities would be responsible for the milk in transit and in the shops. Enough stress had not been put on the time after the milk left the farm.

The Bill was read a second time by 116 to 13.

**Penicillin Production.**—Mr. CHARLES PEAT said on May 18 that small quantities of penicillin in its crude filtrate form could be produced in any bacteriological laboratory. This penicillin could be used for treatment in certain classes of case under special medical supervision. Such laboratories would not be able to make any significant amounts of pure penicillin for general distribution.

### Notes in Brief

The Minister of Health proposes to consult the Mental Hospitals Association before introducing legislation affecting the mental health services of the country.

## Medical News

A meeting of the St. Marylebone Division of the B.M.A., to which all practitioners in the area have been invited, will be held at Marson House, 26, Portland Place, on Monday, June 5, at 5 p.m., to consider the Report of the Council on the White Paper.

A Chadwick lecture on "Vegetation and Human Well-being" will be given on Thursday, June 15, at 4 p.m., at the Chelsea Physic Garden, Swan Walk, S.W.3, by Dr. B. Barnes, head of the department of biology, Chelsea Polytechnic. Particulars may be had from the secretary of the Chadwick Trust, 204, Abbey House, Westminster, S.W.1.

The meeting of the Pathological Society of Great Britain and Ireland which was to be held on July 7 and 8 has been cancelled owing to restrictions on travel.

The annual general meeting of the Society for Relief of Widows and Orphans of Medical Men was held on May 10 with the President, Dr. R. A. Young, in the chair. The report for 1943 was presented and adopted. During the past year 56 widows had been granted relief, receiving a total sum of £4,550. The total membership of the Society was 286. The invested capital now amounts to £141,000. Membership is open to any registered medical man who, at the time of his election, is resident within a twenty-mile radius of Charing Cross; after his election he is at liberty to reside anywhere outside that radius. Relief is granted only to the necessitous widows or orphans of deceased members. At the present time widows over 65 years of age receive £75 per annum, those under 65 receive £60. Last year a Christmas present of £10 was made to each widow. The grants to orphans cease on their attaining the age of 16; there is, however, a special fund from which grants may be made to enable them to study for some professional or business career. Full particulars and application forms for membership may be obtained from the secretary at the offices of the Society, 11, Chandos Street, Cavendish Square, W.1. Members are asked to notify any recent change of address to the secretary.

The thirteenth annual report of the Family Planning Association is a brief document giving an outline of another year of work under war conditions. A week-end instructional school for doctors, arranged by the Sub-fertility Committee, was held last October at North Kensington Women's Welfare Centre and was attended by 40 doctors from all parts of the country. There are now 62 voluntary clinics in Great Britain, of which 55 are run by branches of the F.P.A. A list of these clinics can be had on application to the secretary, at the offices, 69, Eccleston Square, London, S.W.1.

Mr. George H. Law, proprietor of the *Scotsman*, has bequeathed £10,000 to Edinburgh University to be devoted within a year to found a chair of lectureship in orthopaedics. He made other bequests, including £3,000 to the Church of Scotland Deaconess Hospital, £2,000 to Edinburgh Royal Infirmary, and £2,000 to the Royal Edinburgh Hospital for Sick Children.

The Eugenics Society, of which Lord Horder is president and Dr. C. P. Blacker hon. secretary, has issued in pamphlet form a revised version of the aims and objects of the Society. Copies may be had from 69, Eccleston Square, London, S.W.1.

The courses in industrial medicine arranged for July by the Faculty of Medicine of Sheffield University have been postponed owing to the national emergency.

Sir Stanley Woodward, C.M.G., C.B.E., M.D., F.R.C.P., was appointed President of the Royal Institute of Public Health and Hygiene at the annual general meeting held on May 25.

Prof. Alfred Rosset, director of the department of radiology at the Lausanne cantonal hospital, has been elected rector of Lausanne University for the period 1944-6.

The College of Speech Therapists has issued a short printed memorandum on the necessity for making provision for speech therapy among school children. Speech therapy is a medical auxiliary service, and the names of qualified persons appear on the *National Register of Medical Auxiliaries*. The memorandum refers briefly to the effect, the nature, and the incidence of speech disabilities and the reasons for the present neglect of children suffering from them. Out of 315 education authorities in England and Wales, only 104 have appointed speech therapists, while in Scotland only 6 out of 35 have made such appointments. All local authorities responsible for the welfare of children and young people are urged to include in their plans for the future, arrangements for the proper care of those whose speech is defective. The College is prepared to give advice and assistance in this matter to those applying to the secretary, 86, Harley Street, London, W.1.

The following medical prisoners of war have just been repatriated: Lt.-Col. W. E. O. Buchanan, Capt. S. G. Cowper, Capt. W. Mackay Davidson, Capt. C. Donald, Capt. W. Dornan, Capt. J. P. N. Fox, Capt. A. G. Hewer, Col. D. P. Levack, Major F. J. O'Meara, Major A. S. Till.

## EPIDEMIOLOGICAL NOTES

### Discussion of Table

In England and Wales infectious diseases were generally more prevalent, the total for scarlet fever being 145 higher than last week, that for whooping-cough 116, and that for measles 97.

The incidence of scarlet fever rose most markedly in Lancashire and Yorks West Riding, where the total notifications were 52 and 40 respectively above those for last week. Yorks West Riding had 35, and Warwickshire 34, more cases of whooping-cough than they reported last week, but Lancashire had 35 fewer notifications. Kent and Glamorganshire, with the number of notifications respectively 78 and 45 higher, were mainly responsible for the rise in measles incidence. The notifications of diphtheria were 36 above the previous week's total, London's total going up by 20.

Last week's high total for dysentery notifications was exceeded by 21. The chief centres of infection were Lancashire 61 (Blackburn C.B. 38), Cumberland 29 (Penrith U.D. 26), London 21, Derbyshire 15, Essex 14, Warwickshire 12, Shropshire 11, Sussex 11, Middlesex 10, Hertfordshire 10.

In Scotland notifications of measles were 106 higher than last week, those of dysentery 37 fewer. In Glasgow the incidence of measles rose from 301 to 394. Edinburgh reported 21 cases of dysentery, and Glasgow 15.

In Eire the total notifications of measles dropped by 105. The total for paratyphoid includes 56 cases from Dublin C.B. which occurred in institutions from the week ending April 29 and which have only now been reported.

### Quarterly Returns for Scotland

A preliminary statement for the first quarter of 1944 has been issued by the Registrar-General for Scotland. The birth rate was 18.6 per 1,000 and was 0.3 below the rate for the first quarter of 1943 but 0.6 above the average of the previous five March quarters. The infant mortality was 76 per 1,000 and 19 below the five-year average for this quarter, with the exception of 1943, when the rate was 75, this was the lowest infant mortality ever recorded in a first quarter. The maternal mortality was 2.8 per 1,000 live births, being 2.1 below the five-year average and the lowest rate ever recorded for any quarter. The general death rate was 14.4 per 1,000, the same as in the corresponding quarter of 1943 but 2.6 below the average. The death rate from tuberculosis was 88 per 100,000 from all forms, and 65 from the respiratory form. The rate for all forms was the same as the five-year average, but the rate for respiratory tuberculosis was 4 below the average.

### Week Ending May 20

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,733, whooping-cough 2,619, diphtheria 598, measles 2,255, acute pneumonia 806, dysentery 276, paratyphoid 3, typhoid 5.

## INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended May 13.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

### ANY QUESTIONS?

#### Ergotamine Tartrate for Subinvolution

**Q.**—A woman aged 28 has had a slight blood-stained uterine discharge intermittently since the birth of her first child two years ago. There is also a slight degree of prolapse with low backache. I am treating her as a case of subinvolution with ergotamine tartrate, 1 mg. twice daily, in conjunction with glycerin tampons. Is the dose of the drug adequate? How long can it be given continuously without the risk of producing toxic symptoms? How long should the interval be between courses? I would be grateful for further information and advice on treatment. There is no menorrhagia. Periods last about 5 days—no gross irregularity.

**A.**—The characteristic feature of chronic ergot poisoning is gangrene of the extremities. This is caused by a group of alkaloids of which ergotamine is a representative. Cases are recorded in which gangrene of the legs has occurred during the puerperium in patients who have been given ergotamine, but usually these women have also suffered from sepsis, and it is therefore difficult to judge the part played by the drug. Apart from childbirth, ergotamine is often freely used by sufferers from migraine, apparently without ill effects. In view of the known properties of the drug, it is, however, prudent to limit its continued use to doses of 1 mg. twice daily by mouth for periods of not more than one week at a time.

There is no convincing evidence that the continued administration of ergotamine, or any other ergot preparation, influences uterine involution. In any case, it can scarcely be supposed that such therapy would have effect two years after childbirth. Judging from the symptoms as stated, it is probable that this patient's trouble is caused by gynaecological disorder of another variety—possibly of the cervix uteri.

#### Potassium Tellurite Swabs for Diphtheria Diagnosis

**Q.**—Are potassium tellurite swabs efficacious in deciding whether a tonsillar patch is diphtheritic or not?

**A.**—Such swabs are not reliable. Many organisms other than those of true diphtheria—e.g., avirulent diphtheria, some diphtheroids, and other bacteria—reduce tellurite, producing a blackening, and so give false positives. "False negatives" are also met with in practice. The test can in no way take the place of the clinical and bacteriological methods in use. Reliance on the tellurite test would deprive one case in six of necessary immediate serum treatment, and would lead to unnecessary administration of serum to nearly 50% of non-diphtheritic cases. (See *B.M.J.*, 1939, 1, 1273, 1291; 1939, 2, 140; and *J. Amer. med. Ass.*, 1941, 117, 1255.)

#### Prevalence of Bovine Tuberculosis

**Q.**—What percentage of tuberculosis in this country is caused by bovine bacillus? What percentage of the population in the U.K. infected with bovine tuberculosis (a) in the population as a whole (b) school age and under? What are the corresponding figures for Canada and U.S.A., where it is understood the compulsory pasteurization of milk has reduced the incidence by 75%?

**A.**—It is impossible clinically to distinguish between tuberculosis due to human and tuberculosis due to the bovine type of bacillus. The typing of tuberculosis requires skill and time and is not performed as a routine; consequently official figures for the whole country are not available. A recent estimate from the bacteriological evidence of different workers shows that the bovine type is responsible for about 2% of all cases of pulmonary tuberculosis and for about 30% of all cases of non-pulmonary tuberculosis. The proportion varies with the variety of tuberculosis. The bovine form accounts for over three-quarters of the deaths from tuberculosis of the intestines and peritoneum. These values are based on necropsies, etc., and no useful estimation can be made of the amount of bovine infection either in the whole population or at school age and under.

There are considerable geographical differences. Pulmonary tuberculosis of bovine origin is very low in the south of England, becomes commoner towards the north, and in the north-east of Scotland accounts for 10% of all cases of pulmonary tuberculosis. The extent of bovine infection in Canada and the U.S.A. is unknown. Investigations in various cities have shown that with efficient pasteurization the bovine form of tuberculosis tends to disappear. An example of these inquiries is to be found in Toronto, where compulsory notification has been in force since 1915; an investigation did not discover a single case of bovine infection, although 4% of the churn milk and 26% of the bulked milk entering the city contained tubercle bacilli.

#### Dry, Crusty Nares

**Q.**—I have seen a number of patients recently in whom, usually after a cold, a dry, crusty condition of the anterior nares persists. What is the best way of dealing with this very minor but troublesome condition?

**A.**—The soreness and dryness following a cold are best treated by rubbing in a little lanolin twice daily; or, if lanoline is unobtainable, by applying

Ung. hyd. ammon. dil. 3j  
Paraff. moll. ad 3j.

#### Post-operative Morphine

**Q.**—Where rapidity of action, hausea, or vomiting are not important factors, is hypodermic morphine administration generally justified? Where post-operatively morphine is given over 24 to 48 hours, is sublingual dosage four-hourly satisfactory? If given properly, was sublingual dosage satisfactory in the last war?

**A.**—Provided the dosage is suitably increased, the effect of morphine given sublingually can be regarded as satisfactory. The questioner's provisos are, however, very frequently present, and especially is rapidity of action often very advisable. For general post-operative sedation over a period morphine is adequate when administered by mouth, and it was certainly thus used on occasions in the last war. However, the precision of control of dosage and certainly of action of hypodermic injection render this method advisable in ordinary practice.

#### Treatment of Migraine

**Q.**—A married woman of 54 has suffered from migraine since the age of 14. She is getting some relief from drugs. She suffered from hay-fever some years ago, but this has cleared up. She states that her periods ceased 1½ years ago. She is not neurotic and her appetite is fairly good between attacks. She has lost weight during the past 2 years (1-2 stone). I would be glad of any suggestions as to treatment. Attacks (headache, nausea, weakness) are, if anything, increasing in severity and frequency.

**A.**—There are three lines which might be just (but only just) worth following. (1) The patient has an allergic history. It is possible that some cases of migraine are allergic. The patient should therefore have skin tests performed for sensitivity to foreign proteins, and she should be desensitized against any found to be positive. (2) Reports have appeared from time to time of good effects from the injection of the gonadotrophin of pregnancy urine. The evidence that this treatment is useful is not good, but in a case like this, no harm could come from giving it a trial. The suggested dose is 500 rat units twice a week, with a gradual reduction if and when success is achieved. (3) There is rather better evidence that a dehydrating treatment may be useful in some cases, especially when the patient complains of oliguria. The diet should be rich in protein and poor in fat and carbohydrate (a difficult thing to attain in wartime), free from salt, and low in fluids. Urea should be given in a dosage of 25 to 50 g. a day, and other diuretics may be employed. If the above three suggestions fail, it would be worth while seeing whether ergotamine tartrate works sublingually in this patient. If it does, injections can be discarded. This often means that the patient will use the treatment more frequently and earlier and therefore more effectively.

#### Treatment of Keloid Scar

**Q.**—A boy vaccinated about two years ago has developed a keloid, which gave him some pain at first. But he has not complained for the last six months. Is there any risk in not having it treated?

**A.**—Keloid (the purists spell it cheloid from the Greek *chēlē* = claw) is a fibrous overgrowth in the subcutaneous tissue occurring at the site of an intentional or accidental injury to the skin. It is more likely to develop if healing has been accompanied by granulation tissue, as happens in burns or other infected lesions, and there is probably an individual predisposition to it. Histologically the tissue consists mostly of collagen fibrils with scanty fibroblasts, and there is no evidence that this hyperplastic reaction is a precursor of tumour formation. Thus it may be safely left alone. If, however, it is unsightly, or painful due to involvement of superficial nerves, or sufficiently raised to be irritated by clothing, treatment with deep x rays or mild gamma irradiation may be recommended as a reliable method of cure.

# new **'MYOCRISIN'** booklet

A new edition of this much requested publication is now available. Following American investigations on the subject, the pharmacological sections have been re-written and reflect the recent trend of opinion concerning the mode of action of gold from stimulation of the reticulo-endothelial system to the original conception of a direct bacteriostatic or bactericidal action. The gold therapy of rheumatoid and other forms of arthritis is described, as is its use in various dermatoses and other conditions. The reactions which may occur during gold therapy are discussed in their aetiological, prophylactic and therapeutic aspects and there are notes on the erythrocyte sedimentation rate. A bibliography of the more important papers on the different aspects of gold therapy is appended.

A copy of the 'Myocrisin' booklet is free on request for members of the medical profession.

## **'MYOCRISIN'**

TRADE MARK

BRAND

sodium aurothiomalate

MANUFACTURED BY

**MAY & BAKER LTD**

DISTRIBUTORS

**PHARMACEUTICAL SPECIALITIES (MAY & BAKER) LTD DAGENHAM**

7019

TRADE MARK **'SECONAL'** BRAND  
SODIUM PROPYL-METHYL-CARBINYL ALLYL BARBITURATE

**A Rapidly Effective and Short  
Acting Barbiturate for  
Dependable Sedation  
and Hypnosis**

'Seconal' will be found exceptionally useful for medical indications or before surgical procedures where a comparatively rapid and brief acting hypnotic or sedative is required.

'Seconal' is supplied in  $1\frac{1}{2}$  grain and  $\frac{3}{4}$  grain 'Pulvules' brand Filled Capsules in bottles of 40 and 500.

**ELI LILLY AND COMPANY LTD.**  
BASINGSTOKE AND LONDON

followed by a month of practical training in a marine hospital. More than 1,200 have graduated from the school since the end of 1942, and U.S.A. officials estimate that one out of every four merchant ships now has a medical representative aboard. Dovetailing the work of a purser and pharmacist's mate was thought to be the most economical way of providing medical care for the American Merchant Marine. Duties as a purser are heavy when a ship is in port where spare medical facilities are available, but while at sea he has ample time to devote to medical care of men and ship sanitation. Each class entering the hospital school is made up of 40 pursers and ten apprentice seamen. Experienced pursers are not required to attend the purser's school, taking only the medical part of the combined programme. In the Hospital Corps School seamen receive instruction in elementary anatomy and physiology, nursing, and preventive medicine including the giving of inoculations, ship hygiene and sanitation, clinical laboratory work, pharmacy, and advanced first aid. This course is followed by a month in a marine or other approved hospital.

#### Why Tie the Cord?

Dr. E. W. PRICE writes from the Baptist Mission Hospital, Pimu, Belgian Congo: It is more or less assumed in one's medical upbringing in England that failure to tie a newborn baby's cord after section entails considerable risk of fatal or serious haemorrhage. It is therefore surprising to find that among at least one tribe in Africa—one, that is, with which I am familiar—there has never been any attempt to tie the cord in native midwifery. Their use of ligatures, in other medical conditions suggests that if haemorrhage had occurred even a few times the medical tradition would have grown up to ligate the cord, as a preventive. In addition to this observation is the corresponding fact that in seven years' medical experience no case of umbilical haemorrhage has come to my notice. And only one case of umbilical infection. This latter observation is of outstanding significance. The knife used for cutting the cord is never sterile, the subsequent native medicine rubbed on the end of the cord must be far from sterile, and no further dressing or treatment is done. Is it, then, possible that the infection which we do see in England is predisposed to by the devitalization of the tissue distal to the ligature which we habitually place on the divided cord? Further, as the cord separates normally at the skin level and not at the level of the applied ligature, what further call is there to ligate it at all? In imitation of native practice, I have been simply dividing the cord with sterile scissors and putting on a sterile bandage. The results are excellent, and one avoids (a consideration in the conditions of native practice) the need for sterile suture, sterile forceps, and sterile water. It may be that in this one case it is the European who clings to the superstition and the native who knows the truth!

#### Scottish Medicinal Plants

Foxglove leaves, foxglove seeds, and rosehips are again required from the Scottish countryside for medicinal and dietetic purposes. Local arrangements for collecting and dispatching to the Scottish Medicinal Plants Scheme Collection Centre, Airdrie, are in the hands of joint committees of the Women's Voluntary Services and the Scottish Women's Rural Institutes. Details of the scheme are given in a bulletin issued by the Department of Health for Scotland, who advise collectors on how to gather the plants and preserve their valuable content. Foxglove leaves, for instance, are best gathered in late June or July, when the flower is easily recognizable. The essential factor here is that the leaves should be dried as quickly as possible after picking. Foxglove seeds require less attention. They should be gathered about the end of July or August, when half to two-thirds of the capsules on the stalk have begun to split open, and are easily stripped from the plant and later spread on paper in a warm room to dry. A pillow-slip with the mouth fixed open with a hoop makes a good bag for collecting. Scotland's chief contribution to the laboratory is her rosehip crop, and it is hoped that this season will produce even more than last year's bumper crop of 70 tons. The hips are used to make syrup for children and infants to replace the vitamin C normally obtained from oranges and other fruits, and unlimited supplies are wanted. The hips are richest in vitamin content from the time they begin to change colour until they are fully red—normally from September onwards.

#### Vomiting of Pregnancy

Dr. WALTER CALVERT writes: The experience of Dr. Edwards (April 8, p. 512) in vomiting of pregnancy contrasts with my own. I believe, and teach, that many of the physiological and minor pathological phenomena of pregnancy are due to the high blood level of progesterone. This hormone relaxes plain muscle. Thus relaxation of the uterus protects the early pregnancy. Relaxation of the gut gives rise to constipation. Relaxation of blood-vessel walls causes the typical low blood pressure of pregnancy, and the varicose which are seen in various situations. Relaxation of the gastric plain muscle gives rise to vomiting. Accordingly I have

given stilboestrol 1 mg. t.i.d. for 3 days in many cases of vomiting, including quite severe hyperemesis. The results support the theory and are uniformly good. Of course the good results of "treatment" of any kind in these cases are well known.

#### Multiple Infestation with *Taenia saginata*

Dr. G. W. S. ANDREWS and Dr. A. C. OGILVIE, medical officers at an E.M.S. hospital, write: The following case may be of interest for two reasons: (1) Four scolices were recovered after a single dose of filix mas; (2) the present treatment with a single large dose preceded by sodium bicarbonate succeeded, whereas four previous treatments with filix mas in divided doses had been unsuccessful. A domestic servant aged 38 first noticed pain in the epigastrium and distension of the abdomen in Oct., 1942. Two months later white segments were observed in the stools, and she was treated with quassia enemata on two occasions. A few months later she again underwent treatment, this time with filix mas in divided doses. This was repeated three times in seven months. On admission to hospital in May, 1944, she was still passing segments, and treatment with filix mas was again tried. She was given fluids only and magnesium sulphate  $\text{ziv}$  mane for two days. On the third day sodium bicarbonate  $\text{ziii}$  followed 35 minutes later by liquid extract of male fern  $\text{ziss}$  were administered, and finally magnesium sulphate  $\text{ziv}$  after a further half-hour. From the material passed half an hour later a large number of proglottides and four scolices were recovered, which were identified as *Taenia saginata*. The success of this treatment was considered to be partly due to the action of the large dose of sodium bicarbonate in dissolving the mucus which always surrounds the scolex of the tapeworm where it is attached to the mucosa. Our thanks are due to Dr. E. Idris Jones, physician in charge of the case, for advice and help in the preparation of this note.

#### Simulated Epilepsy after Convulsion Therapy

Dr. G. CAMPBELL YOUNG writes from Bracebridge Heath Hospital: Sir Humphry Rolleston once suggested to his class as subject for a thesis—"Diseases caused by Treatment"—a fruitful field indeed. The following is an addition to the already long list. In the absence of my medical superintendent I was asked to see a case at another hospital in the county, a man who was having at least a dozen fits daily and was displaying rather troublesome automatic actions thereafter. Every kind of depressant drug had been given in large doses but without diminishing the number of fits. The case had been referred to a neurological hospital with a view to surgical treatment but had been rejected as unsuitable on the ground that the convulsions were so general that cortical localization was not possible. When I entered the room I recognized a somewhat shadow-like ex-patient of mine to whom I had given a short course of convulsor therapy and who had improved sufficiently to be discharged thirteen months earlier. On his locker was a carefully padded spatula to prevent tongue-biting. He looked at me vacantly and asked me if I were the new medical officer. I requested to be left alone with the patient, and on this happening he immediately said, "You are Dr. Campbell Young," and recalled his stay at Bracebridge and the treatment he had been given. He then described the fits he was having and announced that he would shortly have one, which he obligingly did, with a very fair imitation of a spontaneous or perhaps, more accurately, induced fit. Certification was advised and he again came under care at Bracebridge. All sedatives were withheld. He never had another fit and he is now in the course of being discharged from the R.A.F. Admittedly, the boy was a hysterical type, and had once, in my presence under slight stress indulged in a jaw-clenching, arm-throwing exhibition which, however, would have fooled no one. Even so, it would seem a fair assumption that, had not convulsion therapy been practised, no such orgy of epileptiform attacks would have occurred. Here was a youth aged 22 who had convulsed himself with such success as to convince observers and himself to the extent of risking the excision of part of his cerebral cortex to cure his self-inflicted "epilepsy". It is an interesting corroboration of the imitative faculty of the schizophrenic. The artificially induced convulsion has not apparently been exploited to aid those who coach the less enthusiastic conscript in the art of failing to pass their medical examination. I am indebted to Dr. Macarthur for giving permission for this to be published.

#### Corrigenda

Dr. C. BOWDLER HENRY wishes to correct the last sentence of the paragraph numbered 4 in his letter on "Dental Hygienists" published last week (p. 733). The course referred to occupied half a year, not one year.

A translation into English by Dr. A. Fry of the report by a Committee of Soviet Scientists on "Gas Infection of the Brain as a Form of the Serious Complications of Cerebro-cranial Injuries" was published in the *Journal* of June 26, 1943 (p. 785). A message from Moscow asks us to state that owing to an oversight the name of the author of this report was not given; his name is N. I. Grashchenkov.

## ANALYSIS OF SHOCK

BY

VIRGIL H. MOON, A.B., M.Sc., M.D.

*Professor of Pathology, Jefferson Medical College, Philadelphia, U.S.A.*

During a period of 40 years shock has been the subject of extensive and intensive study, both clinical and experimental. This has resulted in a mass of well-attested factual evidence, but agreement on the pathophysiological mechanisms has not been reached. Writers differ widely in their views, and readers are bewildered by the evidence set forth in support of the conflicting opinions. It appears that a logical correlation of the known facts is needed now rather than a search for new facts. A realistic examination of the causes for disagreement may be illuminating.

## What is Shock?

The broad and indefinite use of this term is not the least among several causes for disagreement. *Shock* has been applied to a number of unrelated conditions. Many regard it as a state of acute circulatory failure characterized clinically by prostration, apathy or stupor, tachycardia, feeble regular pulse, and diminished blood pressure. The peripheral temperature frequently is subnormal. When used in this sense shock includes several forms of circulatory disturbance having no other features in common; their pathogenesis and disorders of function are various. The effects of syncope, fright, exhaustion, anaesthesia, haemorrhage, primary shock, cardiac failure, or of secondary shock may produce the clinical signs mentioned. Each of these conditions may cause low blood pressure; hence it cannot be used as the criterion for differentiating them.

The attention of surgeons is focused chiefly upon shock seen in battle casualties and in those injured in accidents or air raids, and upon shock following extensive surgery. If, under these or other circumstances, a patient manifests the signs mentioned above, shock is regarded as present. Some writers recognize that at least *three unrelated mechanisms* may combine to cause weakness, pallor, feeble rapid pulse, and low blood pressure—interpreted clinically as shock—after traumatic injuries. Attention is invited to a brief consideration of each of these mechanisms.

**Primary or Neurogenic Shock.**—This is a neurovascular reaction like that of syncope or fainting. It may be excited by pain, fear, and the emotional effects of the injury, or by non-sensory nerve impulses arising in the damaged tissues. Primary shock comes on promptly, and is usually transient unless accompanied by extensive trauma or haemorrhage. In cases of severe abdominal injury, visceral perforations, pancreatitis, burns, or extensive damage to other parts, primary shock may merge gradually into secondary shock without an interval of partial recovery. This feature was emphasized by Cope (1928, 1935), Blalock (1940), and others.

Recent experiments (Phemister and associates, 1944) show that prolonged low arterial pressure can be produced in animals by continuous mild stimulation of afferent depressor nerves. Arterial pressures between 40 and 60 mm. Hg were maintained in some instances for several hours. The blood of such animals showed dilution regularly. This feature is opposite to that seen in secondary shock. It indicates that the mechanism of fluid balance is functioning normally and that the capillary walls are not abnormally permeable. Fluid balance and haemoconcentration will be discussed later. A decrease in total blood volume has not been shown in uncomplicated primary shock.

**Haemorrhage.**—The effects of haemorrhage are an obvious cause for low blood pressure and other signs of disturbed circulation after injuries. These signs may develop promptly from voluminous haemorrhage or gradually after slow or repeated small haemorrhages. The clinical signs of haemorrhage are like those of secondary shock, but they differ in other important particulars, as will appear presently. Haemorrhage directly lowers the total blood volume and is followed by a rapid dilution of the blood. This is accomplished by absorption of fluid from the tissues into the blood, tending to restore the blood volume. It is evident that the mechanism of fluid balance is operating physiologically. Low blood pressure developing shortly after trauma is due chiefly to neurogenic and haemorrhagic effects.

**Secondary Shock.**—This is the third mechanism by which circulatory deficiency may develop after extensive injuries. It is due to atony and abnormal permeability of capillary walls, and has been discussed (Moon, 1938a, 1942a, 1942b) as circulatory failure of capillary origin. Products of tissue autolysis or of infection, absorbed from damaged tissues, produce permeability of endothelium like the effects of histamine, peptone, venoms, and other capillary poisons. When this effect is produced in extensive areas it involves the mechanism of fluid balance. Osmosis requires the presence of a semi-permeable membrane—the endothelium. If the latter becomes so permeable that plasma colloids escape through it, osmotic attraction ceases to act and the mechanism of fluid balance is vitally deranged.

Leakage of fluid from the blood into the tissues lowers the blood volume and causes haemoconcentration, which is evidence in itself that the mechanism of fluid balance is not functioning adequately. Under normal conditions fluid lost from the blood is restored by absorption; haemoconcentration is thereby prevented.

Decreased blood volume, combined with increased volume capacity of the capillary bed, tends to cause circulatory deficiency, which is manifested by clinical signs like those of primary shock or the effects of haemorrhage. But the mechanism of capillary damage requires time for development; it is never seen immediately after injury, hence it is called *delayed or secondary shock*.

## Confusion in Shock Analysis

Numerous reports, both from British and from American authors, indicate confusion in attempting to analyse the causes of shock resulting from injuries. Space does not permit detailed examination of each of these. Since the reports are similar in nature and in the conclusion drawn, one will be cited as an example.

Evans and his associates (1944) made haematocrit and blood-volume determinations in 143 cases of knife wounds, bullet wounds, and accidental injuries. Many of these developed shock, as indicated by low blood pressure and other clinical signs. Haemodilution was present in the majority; a few showed haemoconcentration. The authors concluded that low arterial pressure is the most useful criterion for shock and that haemorrhage is its most important cause. It was stated that the injured were seen *soon* after the wounds were received. Hence probably the time factor was not sufficient for the development of secondary shock. In many instances there was haemodilution, and evidence of extensive haemorrhage which averaged 38% of the estimated blood volume. It is probable that primary shock and haemorrhage were chiefly responsible for the low blood pressure.

It seems remarkable that such numerous and important differences escaped the attention of those who have written voluminously on haemorrhages as the cause for shock. More remarkably, a few even advocate haemorrhages as the method of choice for producing shock experimentally. Let it be emphasized that haemorrhages, when present, are a highly important contributory factor; an animal or person in shock may not survive a minor

haemorrhage which under normal conditions would have insignificant effects. But haemorrhages alone, independent of trauma, anaesthesia, or toxic effects, will not produce the syndrome of secondary shock.

#### Contrasted Features

Items	Shock	Haemorrhages
Endothelium .. .. .	Permeable to colloids	Impermeable
Flow of lymph .. .. .	Increased	Decreased
Tissue fluid .. .. .		
Fluid balance .. .. .	Disturbed	Undisturbed

#### Circulatory Dynamics

The principles of capillary physiology (Starling, 1909; Ebbecke, 1923; Lewis, 1927; Krogh, 1929) serve to explain how various noxious agents produce circulatory deficiency. A diversified group of substances which affect endothelium deleteriously are known as capillary poisons. These include extracts of normal tissues, products of tissue autolysis, foreign proteins and protein-split products, bacterial substances, histamine, bile, venoms, poisons, metabolic products, and even moderate lack of oxygen. It was established that any kind of injury to endothelium increases its permeability to the plasma colloids. Thereby other dysfunctions result as shown in the following table:

Agents or conditions injurious to endothelium	Pathological effects:
	Endothelial permeability
	Disturbance of fluid balance
	Oedema of soft tissues
	Serous effusions
	Increased flow of lymph
	Haemoconcentration
	Capillo-venous congestion
	Stasis
	Petechial haemorrhages

Permeability of capillary endothelium lowers both the actual and the effective blood volume. Leakage of plasma into the tissue spaces reduces the *actual* blood volume and causes haemoconcentration, while sequestration of blood by stasis in dilated capillaries and venules reduces the *effective* blood volume. This combination leads to a disparity between the volume of blood and the volume capacity of the vascular bed. Such a disparity produces a circulatory deficiency superficially resembling that resulting from haemorrhages. Physiological reactions compensate for minor degrees of such a deficiency. Activity of the sympatho-adrenal system causes arterial constriction, stimulates cardiac function, and causes the spleen to contract, discharging its reserve of blood into the circulation. Selective distribution of blood favours the vital organs at the expense of non-vital parts. Peripheral circulation is reduced, and the external parts become pale, cold, and almost-pulseless.

So long as this compensation is effective there is no marked decline in the arterial blood pressure, but the latter is maintained at the expense of the volume flow. Stagnation of circulation in the dilated capillaries reduces the amount of venous blood returned to the heart. This lessens the cardiac output and decreases further the volume flow. A reduced delivery of oxygen to the tissues follows, with accompanying anoxia, which of itself causes further relaxation and permeability of capillary endothelium (Krogh, 1929; Landis, 1934, 1937). This feature introduces a self-perpetuating factor into the mechanism, causing it to progress in a vicious circle. When finally the compensatory reactions are no longer adequate the blood pressure declines progressively

and the complete syndrome of shock is manifested clinically. The items which constitute that syndrome were tabulated above in the comparison between shock and the effects of haemorrhages.

Circulatory deficiency originating in the capillaries produces the pattern of visible changes in the viscera described in a preceding section. The capillaries and venules become relaxed and distended with closely packed corpuscles, stagnation of circulation develops; stasis is the surest sign of increased capillary permeability (Landis, 1934, 1937). The leakage of plasma causes oedema of soft tissues and effusions into serous cavities. Dissolution of capillary walls causes minute haemorrhages in mucous and serous surfaces and in parenchymatous tissues. These changes are seen in varying degrees when secondary shock from any cause has been the major factor leading to death.

We have noted that marked hyperaemia and petechial haemorrhages predominate when severe shock has led to death in a few hours. Serous effusions and oedema are prominent when the deficiency has developed more gradually, leading to death after 24 hours or longer. We were able to produce pulmonary oedema experimentally (Moon and Morgan, 1936) by burns of moderate extent, by tissue autolysis *in vivo*, and by injections of various capillary poisons. To accomplish this it was only necessary to decrease the dosage of the agent so that fatal circulatory failure might develop more slowly. Partial circulatory stasis and oedema of the lungs predispose to pneumonia. We have reported (Moon, 1938b) on secondary pneumonia as a terminal event in shock of sublethal degree.

#### Half-truths

Erroneous beliefs persist longer when supported in part by truth than when entirely false. Propaganda is far more effective when based upon a modicum of fact; likewise in scientific matters. One example has been seen in the belief that shock from trauma is due entirely to haemorrhage. Another instance is the interpretation that leakage of plasma locally is the cause for low plasma volume.

The decreased plasma volume which develops after burns is attributed by many writers entirely to capillary leakage in and about the burned area. Scant attention is paid to the fact that capillo-venous hyperaemia and oedema develop in extensive visceral areas remote from the burn. Long ago it was shown (Schjerning, 1884; Bardeen, 1896-7, 1897; Pack, 1926) that the brain and meninges, the lungs, gastro-intestinal tract, liver, and kidneys are markedly hyperaemic, that the soft tissues are oedematous, and that petechial haemorrhages are found in the serous surfaces, mucous membranes, and parenchymatous tissues of the viscera.

These changes are the characteristic pathological finding after death from burns. Yet some ignore them, unwilling to admit the systemic effects of substances absorbed from burned tissues. It is true that local loss of fluid occurs about injured tissues; but it is equally true that such loss occurs also in visceral areas after extensive burns or trauma. Local fluid loss is only part of the mechanism by which plasma volume is reduced.

Some writers attribute the visceral hyperaemia and oedema to anoxia, and explain that they occur during the agonal period just before death. Clinicians who have listened to the breathing of severely burned patients testify to the presence of congestion and oedema when shock is present *before the agonal stage is reached*. It is true that anoxia will cause capillary atony accompanied by hyperaemia, stasis, and oedema. But this is not a complete picture of the relationship. Capillary atony and anoxia have reciprocal effects: either of them acting primarily will bring about the development of the other. This relationship gives the disturbance a self-perpetuating quality which operates in a vicious circle.

So long as the physiological mechanism of fluid balance is functioning, local fluid loss is compensated by the absorption of fluid from the tissues elsewhere. This maintains the blood volume and concentration within normal limits. For example, large amounts of fluid may be lost from the blood locally, as in hydrothorax or ascites, yet neither shock nor haemoconcentration follows. It is my belief that haemoconcentration is evidence of capillary permeability sufficient in extent and degree to disturb the mechanism of fluid balance. This may at times result from the *local* effects of burns or trauma of great extent. It probably will not develop from limited injuries.

Any loss of blood or fluid is of importance when secondary shock threatens to develop. The importance of the local loss is in proportion to the amount of fluid loss. The explanation of low plasma volume and haemoconcentration as resulting from local fluid loss is another instance of a part-truth.

### Traumatic Toxaemia

During World War I the British Medical Research Committee organized a co-ordinated clinical and experimental investigation of shock following wounds. Eminent British, French, and American workers studied the manifestations seen in injured men and in experimental animals. These reports led to the theory known as *traumatic toxaemia*. It is summarized as follows:

"The theory of secondary shock which has the strongest support, both in clinical observations and in laboratory experiments, is that of a toxic factor, arising from damaged and dying tissue and operating to cause an increased permeability of the capillary walls and a consequent reduction of blood volume by escape of plasma into the lymph spaces. Thus the concentration of the corpuscles is also readily explained. It is recognized that, after a sufficient time, infection may occur and be of such character in itself as to induce a persistent low blood pressure. According to this theory there may be no essential difference between the effects of toxins given off by damaged tissue and of toxins resulting from activity of bacteria." (Med. Dept. of U.S. Army in the World War, 1927.)

The chief objection to this explanation is negative in character, based on the fact that no toxic substances had been shown experimentally or identified chemically in the blood during shock. Digressing for a moment, let it be noted that the same objections and logic apply equally to the bites of venomous snakes. No toxic substance has been identified chemically in the bitten animal's blood; I have seen no report on transfusion of blood from a bitten animal to a normal one; it is highly improbable that the amount of venom so transferred would cause notable effects. The bitten limb swells enormously and its tissues are distended with blood and fluid. May not the effects of a snake-bite be due entirely to local loss of blood and fluid in the area affected? This explanation would make unnecessary the assumption that a toxic substance produces systemic effects after snake-bites.

Presumably the toxic substances which result from trauma are cleavage products of tissue autolysis or of bacterial action upon tissue proteins. Chemical methods are not yet perfected to identify such substances in the blood, except as non-protein nitrogen. The latter is markedly increased during shock, and is attributed (Whipple and van Slyke, 1918; Whipple *et al.*, 1920) to destruction of the body's proteins. The objection mentioned took no account of these facts nor of the mass of clinical and pharmacological evidence indicating toxic effects.

Recent reports indicate toxaemic effects in experimental traumatic shock. Best and Solandt (1940) instituted exchange transfusion of blood between pairs of dogs, in one of which shock was induced by trauma. The untraumatized dogs developed shock, as did those traumatized. These results were interpreted as indicating the effects of a toxic substance released from injured tissues and conveyed by the blood. Kendrick, Essex, and Helmholz (1940) performed a somewhat similar experiment by exchange transfusion, which likewise furnished evidence supporting the theory of toxaemia. Even those who have opposed vigorously the conception of a toxic factor have now relaxed their opposition. For example, Frecman and his collaborators (1941) reported experiments on traumatic shock which they interpreted as indicating the effects of a toxic factor absorbed from the traumatized region.

This view is in agreement with an enormous mass of clinical and experimental data. It is based upon sound physiological principles and it is supported by necropsy findings. The pattern of circulatory changes seen in the viscera after secondary shock is of unmistakable significance. These changes indicate the origin and nature of the circulatory deficiency. The recognition of a toxaemic factor in secondary shock will abolish the most important cause for disagreement. Investigations on other features can then go forward in an atmosphere cleared of controversial discussions.

The basic principles on which agreement may be expected are as follows: Surgical shock, like that resulting from extensive trauma, is not due to a single cause but to a combination of causes: the anaesthetic, the local loss of blood and fluid, emotional

reactions, infection, or intoxication which may have reduced the patient's physiological state; the disease itself, which necessitated operation; and the absorption of toxic products from traumatized tissues. The relative importance of these factors varies in each case, and they operate in varying combinations. Some of these factors are lacking in shock from other causes.

It is now recognized that the occurrence of shock is not limited to traumatic injuries, burns, and the aftermath of extensive surgery. I have emphasized repeatedly that the same mechanisms operate in severe infections, metabolic intoxications, abdominal emergencies such as intestinal strangulation, mesenteric thrombosis, perforation, peritonitis, and from the effects of poisons.

### Renal Dysfunction

Deficiency of renal function is an item of importance in secondary shock from diverse causes. For example, extensive burns are followed promptly by oliguria or anuria, by a progressive accumulation of nitrogenous wastes in the blood, and by casts, red cells, pigment, debris, albumin, and other abnormal findings in the urine. This condition persists so long as the state of shock continues, and renal deficiency becomes prominent when patients survive for several days in a state of sublethal shock (Moon, 1942a). The excretion is inadequate, the non-protein nitrogen rises progressively, hyperazotaemia develops, and the clinical syndrome of uraemia often precedes death. Similar renal disturbance occurs in secondary shock from trauma, after extensive operative procedures, intestinal obstruction, metabolic intoxication as in diabetes, icterus gravis, toxaemia complicating pregnancy, anaphylactic reactions, transfusion with incompatible blood, poisoning with various drugs, and in severe infections.

An instance of sublethal shock leading to azotemia is that of the crush syndrome which Bywaters (1942) and others have reported. Victims of air raids had been pinioned under masonry and debris for hours. When rescued they developed signs of shock, which were counteracted by modern treatment. Despite the fact that adequate systemic circulation was maintained, these cases developed the complete syndrome of uraemia, and many died from progressive renal deficiency. When recovery occurred oliguria gave place to polyuria rather suddenly, renal function was resumed, and the non-protein nitrogen declined to a normal level. The findings at necropsy in some instances included congestion and oedema of the lungs and other viscera, as seen in secondary shock; in other cases the visceral appearances were not described. The traumatized muscles were pale, friable, and necrotic. The kidneys were pale, swollen, streaked with red and brown. The convoluted tubules showed varying degrees of degeneration, necrosis, and desquamation. The lumina contained hyaline casts, debris, and masses of brown pigment. This was shown spectroscopically to be myoglobin: its source as derived from damaged muscle is *prima facie* evidence of absorption from the traumatized areas.

This type of renal disorder was known to Osler and his contemporaries as "acute parenchymatous nephritis." They recognized its occurrence under several of the conditions previously mentioned. The syndrome is usually discussed as "extrarenal uraemia" by clinicians. Its pathology is not adequately presented in treatises on renal disease. Some describe it under "tubular disease," others under "nephrosis."

The exact nature and pathogenesis of renal failure accompanied by parenchymatous degeneration and necrosis in otherwise normal kidneys, as a complication of sublethal shock, is a subject for future investigations. There is suggestive evidence that the same injurious agents, including toxins and anoxia, which cause circulatory failure by their effects upon endothelium, likewise cause renal failure by their effects upon the parenchyma of the kidneys.

### Practical Considerations

"The best treatment for shock is prevention." To accomplish this it is essential to know the various conditions under which shock may develop. Hence not only after trauma, extensive surgery, or burns; but also in severe infections and intoxications, and in abdominal emergencies such as thrombosis, strangulation, perforation, and the like, the anticipation of shock may make its prevention possible.

Early amputation of mangled limbs, débridement of lacerated wounds, prompt local treatment of burns as by coagulation, surgical relief of an infarcted or strangulated loop of bowel, and the drainage of infected areas are procedures which may forestall the development of shock. Likewise the prevention of infection, by therapeutic or other means, removes a potent contributory factor. The careful surgeon reduces the danger of shock by reducing to the minimum both the depth and the duration of anaesthesia and by using regional or local anaesthesia when possible. General anaesthesia usually will not of itself cause shock, but it often leaves a narrow margin of safety when combined with other shock-producing conditions.

The successful management of secondary shock requires primarily that the conditions which caused it shall be obviated or removed; otherwise, efforts to restore the failing circulation are predestined to failure. For example, unlimited quantities of plasma probably would not prevent death from intestinal strangulation or from a crushed and mangled limb unless the causative condition could be obviated effectively.

### Traumatic Shock

The clinical signs of shock often develop after injuries of various kinds and degrees. Weakness, pallor, circulatory deficiency, rapid pulse, and low blood pressure are prominent features, but unfortunately these do not aid in determining either the type of the circulatory disturbance or the mechanism by which it developed. Those in whom these features are marked, apparently indicating severe circulatory failure, often recover promptly under appropriate treatment while others whose apparent condition is not alarming—they may even be ambulatory—may develop circulatory deficiency which progresses to a fatal termination despite all counteractive measures.

Experiences of this kind are well known to those dealing with accidental injuries. They have been noted especially among civilian casualties from air raids. Much confusion arises from the fact that many surgeons regard so-called *traumatic shock* as a disease entity. In reality it is nothing more than a symptom-complex, which is not a dependable index either of the nature of the disturbance or of its severity. When this syndrome is seen after injuries it is essential to differentiate between three conditions which may be operating singly or in combination. These are:

1. Primary or neurogenic shock, which may appear extremely grave and yet lead to prompt recovery. If the victim is seen within an hour or two after the injury, if the character and location of the wounds do not indicate considerable haemorrhage, and if examination of the blood does not show notable dilution or concentration, it is safe to assume that primary shock is the major factor. Any wounds should receive appropriate care, and enough morphine should be given to allay pain and apprehension. After rest, warmth, and ingestion of fluids, recovery from primary shock is usually prompt. The experiences of surgeons indicate that anaesthesia and operative procedures should be postponed, except emergency measures, until the patient reacts from the depressed circulation. In World War I special "shock teams" were employed in casualty clearing stations and field hospitals. They supplied dry clothing, administered stimulants, heat, warm drinks, and liquid nourishment. These measures were effective in the relief of primary shock in preparing the wounded for operation.
2. When loss of blood has been considerable the clinical signs will be like those in other forms of circulatory failure. If the person is seen within a few hours after the injury these signs probably represent the combined effects of primary shock and of haemorrhage. Examination of the blood may show which of these is the major factor. Haemodilution occurs promptly after haemorrhages; the degree of this is an approximate index of the amount of blood lost. Reports on large numbers of accidental injuries and casualties from air raids show that haemodilution is usually present. The conclusion that haemorrhage is the major factor in such cases is not open to question. The local treatment of the wounds and the restoration of blood volume, preferably by transfusion of whole blood, do not require consideration here. Cases of primary shock as haemorrhage, if not accompanied by extensive trauma, may show marked circulatory deficiency clinically, but they usually respond readily to treatment. A tendency to progress towards a fatal termination despite treatment is not a characteristic of such cases.
3. Delayed or secondary shock results from factors other than those which cause either primary or haemorrhagic shock. The fact that their clinical signs are the same is the chief source of confusion regarding shock following trauma. This condition requires time for development: except with cranial or abdominal injuries or extensive

burns, it is seldom seen until 4 or 5 hours after the injury. The chief cause for secondary shock is the absorption of toxic substances from damaged tissues. These substances originate in part from autolysis, in part from bacterial growth.

All accidental and battle wounds are grossly contaminated; bacteria, both pathogenic and saprophytic, multiply readily in the debris of damaged tissues. Probably the products of bacterial growth are more toxic than those of simple tissue autolysis. For example, shock developed more slowly and in less degree in crush injuries which were not accompanied by open wounds. When a similar amount of muscle tissue has been damaged and laid open, as by a shell fragment, the development of shock is more rapid and severe. Perhaps this is because products of bacterial growth are important factors in the latter instance.

It has been observed (Cope, 1928, 1935; Blalock, 1940) that a fall in blood pressure is not an adequate criterion for incipient secondary shock. Frequently, circulatory deficiency is developing while the blood pressure is well maintained or is even at its highest recorded point. So long as the mechanism of compensation is effective there is no marked decline of the arterial pressure; the latter indicates that the mechanism of compensation is failing and that the condition is becoming critical. An ominous fall in blood pressure is not a sign of incipient secondary shock; too often it is a sign of departed opportunity.

As stated earlier in this paper, secondary shock is accompanied by a disturbance of fluid balance which results from abnormal endothelial permeability. This disturbance affects the mechanism of absorption. Fluids given orally or subcutaneously are not absorbed. Thirst becomes incessant, but efforts to relieve it are followed by vomiting. The fluid vomited is often in excess of that swallowed, and the vomitus in this condition contains brown flecks—"coffee grounds" vomitus. These flecks contain haemoglobin: they result from capillary haemorrhages in the gastric mucosa.

### Haemoconcentration

Abnormal endothelial permeability which disturbs fluid balance results in haemoconcentration—a distinguishing feature in this type of shock. This feature is valuable both in recognizing the type of circulatory deficiency and in noting its progress. Haemoconcentration may be shown by counts of erythrocytes, by haemoglobin readings, by haematocrit, or by the specific gravity of the whole blood. My personal preference is for erythrocyte counts. Whichever method is used, a reading should be made when the injured person is first seen. Subsequent readings at intervals of one to three hours will furnish valuable evidence as to the nature and progress of the condition.

Unfortunately haemoconcentration may be masked by the haemodilution resulting from associated haemorrhages. Also, the victim may have had some degree of anaemia before the injury. For example, an erythrocyte count of 5,000,000 appears normal, but in one whose previous count was 3,500,000 it would indicate more than 40% haemoconcentration.

If the first examination shows moderate haemodilution it is apparent that haemorrhage is the major factor; subsequent findings of the same degree or of lower dilution would likewise indicate haemorrhage. But in the same case a subsequent finding of a higher concentration some hours after the injury indicates that secondary shock is developing in one previously affected by haemorrhage or perhaps by anaemia. If a person seen for the first time four hours or longer after injury shows clinical signs of shock not accompanied by haemodilution, it suggests that neither primary shock nor haemorrhage is the cause. Inadequate circulation developing some hours after injury, with approximately a normal concentration of the blood, is strongly presumptive of secondary shock in one who has lost blood by haemorrhage, or perhaps in a previously anaemic person.

The incipient stage of secondary shock unaccompanied by haemorrhage may be detected by the presence of moderate haemoconcentration—10 to 20%—even before evidence of circulatory deficiency is manifested clinically. This is seen frequently within an hour or two after extensive burns because shock develops faster after burns than after other injuries. If a subsequent examination of the blood shows a higher degree of concentration it indicates progress in the development of shock even though the arterial pressure may not be ominously low.

In order to treat the patient intelligently it is of advantage to know which condition or combination of conditions is responsible for the circulatory deficiency. A consideration of the time factor plus observations on the concentration of the blood may be distinctly helpful.

### Treatment

Several therapeutic misconceptions are prevalent concerning the treatment of secondary shock. There is no apparent basis for the belief that morphine is useful in counteraction or prevention. On the contrary, morphine is dangerous when given in full doses because it inhibits respiration and thereby increases anoxia, which is a major factor in this condition. Enough morphine should be given to allay pain and apprehension, but amounts sufficient to lower the respiratory rate will accelerate the development of secondary shock.

Experience has shown that stimulants, such as digitalis, strychnine, and adrenaline, not only are useless but may be distinctly harmful. Cardiac deficiency is not a factor in the development of secondary shock; the vasomotor system is active and the peripheral arteries are already contracted to the maximum. Under such conditions adrenaline cannot be expected to produce benefit, and it should be remembered that large or repeated doses will actually cause shock in experimental animals.

Another matter deserving thoughtful consideration is the application of heat in attempts to prevent or to counteract shock. It is natural that physicians should note the low peripheral circulation and temperature and should try to relieve them artificially. The application of heat is widely practised, perhaps without due consideration of the physiological principles involved. During shock and after haemorrhage the blood volume is reduced. There is not sufficient blood to fill the entire vascular bed and to support metabolism throughout the body. Physiological reactions compensate for this condition by a selective redistribution of blood, favouring vital organs at the expense of the external parts. The vascular channels in non-vital areas become collapsed and bloodless, but both circulation and metabolism are maintained where they are most needed.

It is possible to open up the peripheral vascular bed by the application of heat and stimulants. But this counteracts Nature's mechanism for conservation: the blood required to restore circulation in the external areas lowers needlessly the already depleted reserve of blood. Recent evidence, both experimental and clinical, indicates that the use of heat in the treatment of shock causes further circulatory deficiency and that the results are detrimental.

Those remedies which have proved useful are agents which tend to counteract one or another of the major items by which secondary shock develops or progresses; chief among these items are anoxia, endothelial permeability, and reduced blood volume. Lack of oxygen accelerates the development and progress of shock. The inhalation of oxygen aids in counteracting this and in preventing irreparable damage. It raises metabolic activity and tends to interrupt the action of the vicious circle even after shock has been initiated.

Physiological studies indicate that one function of the adrenal cortical hormone is to maintain the normal impermeability of endothelium. There is significant evidence, both experimental and clinical, that this substance is distinctly beneficial in the prevention and in the treatment of shock from burns (Wilson *et al.*, 1936; Rhoads *et al.*, 1941).

The successful treatment of shock requires, first, that the condition which caused it shall be removed; next, that the fluid which was lost from the blood be replaced by fluid which should approximate closely the composition of that lost. Thus after serious haemorrhages transfusions of whole blood provide the ideal remedy. But in shock accompanied by haemoconcentration whole blood is not so suitable; it does not relieve the haemoconcentration, which, because of viscosity, tends to impede circulation through the capillaries. The patient does not lack erythrocytes, but he sorely needs fluid to restore the blood to its normal composition and volume. These considerations indicate clearly that the ideal replacement fluid is either human plasma or serum.

These substances are now available in most hospitals and medical centres, either in the original form or concentrated or dehydrated. Plasma or serum, given in the normal or isotonic concentration, serves admirably as a replacement fluid to restore blood volume and to reduce haemoconcentration. But the same amount of plasma, concentrated to one-half or even to one-fifth of its original volume, is far more effective in counteracting both the low blood volume and the deranged equilibrium of fluids

which are prominent factors in the mechanism by which shock develops (Hill and Muirhead, 1942).

Concentrated plasma or serum, given intravenously, raises the osmotic pressure of the blood and thereby draws fluid from the tissues into the vascular system. This accomplishes several desirable results: it increases directly the total blood volume; it relieves the haemoconcentration, reduces the viscosity of the blood, and restores fluid balance; it tends to reduce the oedema of soft tissues; it also relieves the hypoproteinaemia which often is a notable feature. These effects increase the circulatory efficiency and the delivery of oxygen to the tissues. The relief of anoxia removes a most important factor from the vicious circle by which the deficiency progresses.

The foregoing considerations are not based upon personal experiences. They represent an analysis of the mechanism involved and a comparison of these with the recorded experience of physicians and surgeons.

Let it be emphasized that early recognition and treatment at or of the highest importance if favourable results are to be hoped for. Treatment, to be effective, must anticipate the complicated interplay of the agencies whose combined effects culminate in the syndrome of shock. It must be administered before the failing circulation and the associated anoxia have produced irreversible changes in tissues whose functions are vital.

### Summary

Confusion arises from the fact that three unrelated mechanisms may cause the clinical signs of shock following injuries. These are: primary or neurogenic shock, the effects of haemorrhage, and delayed or secondary shock. These may operate singly or in combination.

Traumatic shock is not a disease entity but a syndrome. It represents the summative effects of the three conditions mentioned. Each of these causes low arterial pressure, hence they cannot be distinguished by that criterion.

The physiological disturbances which accompany secondary shock are not the same as those of haemorrhage. Simple uncomplicated haemorrhages apparently will not produce this syndrome. But haemorrhage, when present, is a highly important contributory factor: a person in whom secondary shock is developing may not withstand the loss of an amount of blood which would be insignificant in an otherwise normal person.

Loss of capillary tone and abnormal permeability of endothelium are important factors in secondary shock. These have not been shown to play a part either in primary shock or in the effects of haemorrhage. Abnormal permeability disturbs the mechanism of fluid balance, leading to oedema of the viscera and to haemoconcentration.

A serious derangement of renal function accompanies secondary shock. This is seen not only after injuries and burns but also from the effects of intestinal obstruction, mesenteric thrombosis, metabolic intoxications, anaphylaxis, transfusion reactions, severe infections, and from the effects of various poisons. Patients who survive several days in a state of sublethal shock frequently develop the syndrome of uraemia and die of renal dysfunction.

The clinical management of shock requires the recognition of the causative mechanism. Cases of primary or haemorrhagic shock, unless accompanied by extensive trauma, respond more readily to treatment than do those of advanced secondary shock.

Observations on the concentration of the blood and a consideration of the elapsed time since the injury are valuable aids in determining which mechanism is the major factor causing circulatory deficiency.

Loss of blood volume is an outstanding feature after haemorrhages and in secondary shock. The one is best treated by transfusion of whole blood; the other by plasma or serum.

## MENINGITIS DUE TO PITTMAN AND NON-PITTMAN STRAINS OF H. INFLUENZAE

BY

J. GORDON, M.D., D.P.H., M.R.C.P.

Senior Lecturer in Bacteriology, University of Leeds

HESTER E. de C. WOODCOCK, M.B., D.P.H.  
Acting Medical Superintendent, Fever Hospital, Leeds

AND

K. ZINNEMANN, M.D.

Lecturer in Bacteriology, University of Leeds

For the last few years treatment with sulphonamides has been extensively applied to cases of meningitis due to *H. influenzae*. In this country several cases treated successfully in this way have been recorded: Jones (1937), Teggart (1938), Roberts (1939), Sakula (1940), Harold (1941), Jacoby (1941), Archer and Singer (1943), Birch (1943), and Matthews (1943). None of these reports give any clue as to the serological type of the *H. influenzae* strains isolated. Two reports have been published in this country about unsuccessful treatment with sulphonamides of meningitis due to *H. influenzae*—Mackenzie, Page, and Ward (1940) and Jones and Sudds (1942). The latter paper is the only one in which a serological examination of the organism responsible was carried out; the culture was of the b type (Pittman, 1931).

A third group of papers give accounts of both successes and failures in *H. influenzae* meningitis (serological types not given) using the sulphonamides for treatment: Mutch (1941), Davies (1943), and Moir (1943). Davies and Moir, however, emphasize the importance of using large doses of these drugs at an early stage. Moir also stresses their continued use after meningeal symptoms have disappeared, in order to avoid relapses. Mutch has suggested that strains isolated in this country should be examined not only culturally but also serologically. Mutch and Davies are not very favourably impressed by the curative value of these drugs in this condition, particularly with infants.

### American Views on Treatment

American publications on this subject are more numerous, and several reviews have been published: Bigler and Haralambie (1939), Aléman (1940), Neal, Appelbaum, and Jackson (1940), Lindsay, Rice, and Selinger (1940), Alexander (1941), Mitchell (1941), Neter (1942), Alexander, Ellis, and Leidy (1942), and Knouf, Mitchell, and Hamilton (1942). The general tone of the reviews is that sulphapyridine is more useful than sulphaniilamide in the treatment of these cases, and some authors claim that the combination of an antiserum to *H. influenzae* and sulphapyridine provides the best form of treatment available at present. Neal, Appelbaum, and Jackson (1940) reported on 29 patients, 20 of whom were treated with this combination, 9 being given sulphapyridine alone. Of the 29 patients 14 recovered. The mortality rate was therefore 52%. Of the

14 patients recovered 5 had received the drug alone. Lindsay, Rice, and Selinger (1940), in reviewing 108 cases, showed that treatment with antisera reduced the mortality from 97% to 83%: by adding sulphaniilamide and sulphapyridine the mortality for 13 cases was further reduced to 54%. Knouf, Mitchell, and Hamilton (1942) report altogether on four comparable series of 63 patients treated during the last 10 years. Group 1 consisted of 19 patients treated only symptomatically. In this group all patients died. Group 2 also had 19 patients. These were treated with anti-influenza serum. All died. In Group 3, which consisted of 13 sulphaniilamide-treated patients, there was one survivor. Group 4 was made up of 12 patients, with 9 survivors, or a mortality of 25%. The patients in this group were treated with sulphapyridine.

### Strains of *H. influenzae*

Pittman (1931) had shown that the majority of *H. influenzae* strains isolated from meningitis cases in the United States belonged to a special group of this organism, which is characterized by possessing a capsule consisting of carbohydrates. This capsule has antigenic properties. Six different types of capsular antigens can be differentiated, and the American meningitis strains belong mostly to Type b. According to Pittman capsulated strains have a smooth appearance, but the colonies are rough when the strains lose their capsules, whereas the strains usually isolated from the respiratory tract are non-type-specific and have a rough appearance when first isolated. Fothergill and Chandler (1936), on the strength of virulence and agglutination experiments on dissociated smooth strains, regarded all rough strains as avirulent variants of *H. influenzae*. Pittman (1939) could protect mice easily with sulphapyridine against infection with *H. influenzae* (non-type-specific). Pittman (1942), using *H. influenzae* (Type b) and confirming the findings of Povitzky (1937) with meningeal strains, showed that in experimental infections of mice the combination of antiserum and sulphapyridine gave a higher percentage of cures than either of these substances alone. Pittman (1942) also found sulphaniilamide not very effective as compared with sulphapyridine, sulphathiazole, and sulphadiazine; furthermore, that several strains of *H. influenzae* (Type b) showed different sensitivity to the drugs. There are two fatal meningitis cases on record (Pittman, 1933; Mulder, 1939) in which rough strains (non-type-specific) were isolated from the cerebrospinal fluid. Neither of these two cases was treated with sulphaniilamide or any of its compounds. Pittman (1931) has shown that rough strains, and Allison, Gordon, and Zinnemann (1943) have shown that respiratory strains not belonging to the Pittman types, are virulent for white mice, although this virulence is lower than that of strains of the Pittman types. In view, therefore, of the small number of cases reported as being due to non-capsulated strains of *H. influenzae*, and their theoretical importance, we are recording the following cases of meningitis, which responded very well to sulphapyridine and which could be shown not to belong to any of the Pittman types.

### Non-Pittman Type of Meningitis treated with Sulphapyridine

Case 1.—G. R., aged 7. Fell from tricycle Aug. 14, 1942. Persistent headache and vomiting since. On admission, Aug. 21, T. 97.6°, P. 92, R. 20; appeared fairly well; quiet. Pupils equal, reacted briskly. Some neck rigidity. Abdominal reflexes equal and active. Knee-jerks—R. normal, L. almost absent. Triceps jerks equal. No Kernig, no Brudzinski, no Babinski. Tone of limbs normal. Swelling size of a walnut L. occipital region. Lumbar puncture: 10 c.cm. fluid removed; no increase of pressure; fluid slightly turbid. Aug. 22: Mentally very bright; no pain; neck rigidity marked; Brudzinski positive; Kernig negative, but test causes obvious pain; knee-jerks not obtained; T. 100°, P. 114, R. 22. Aug. 23: Neck rigidity less; T. normal, and never raised again. Aug. 24: Cyanosis (from sulphapyridine). Aug. 25: Neck rigidity almost gone. Aug. 27: No neck rigidity; no knee-jerks, otherwise appeared normal. Sept. 5: Discharged quite well. Treatment:—Aug. 21: Sulphapyridine 2 g. (4 tablets) stat.; 1.5 g. four-hourly for 24 hours; alkaline mixture (pot. cit. gr. 40, sod. bic. gr. 20) given four-hourly along with sulphapyridine. Aug. 22: Sulphapyridine 1 g. four-hourly. Aug. 24: Sulphapyridine 0.5 g. four-hourly. Aug. 26: Sulphapyridine discontinued. Total dose of sulphapyridine, 26 g.

Case 2.—T. S., aged 5. Admitted March 3, 1943. Since March 1 had had headache and vomiting. On admission did not seem ill;

these is the sulphonamide or para-amino-phenyl-sulphonic radical,  $\text{NH}_2\cdot\text{C}_6\text{H}_4\cdot\text{SO}_2\cdot$ . Of the 40 cases 16 were of this type. Two cases not included in this group, however, behaved in a peculiar manner. They were both eczemas, highly sensitive to small doses of sulphanilamide but not to small doses of other sulphonamides. Each of them reacted to other sulphonamides in heavy dosage, with mild eruptions only. This reaction included a selective flare-up of the sites of previously positive sulphanilamide skin tests, but not of the negative tests to other sulphonamides. Had they been allergic to the sulphonamide group they should have reacted to all these in roughly equal amounts (1 g. of sulphanilamide or sulphanilic acid is equivalent to about 1.5 g. of sulphapyridine or sulphathiazole). The marked difference suggests that a small quantity of sulphanilamide or closely related compound may be formed in the body from the other sulphonamide drugs.

**Allergy to Other Drugs.**—Rogers (1938) described a case in which the administration of sulphanilamide caused a flare-up of the sites of several previous reactions to procaine. Procaine has the formula  $\text{NH}_2\cdot\text{C}_6\text{H}_4\cdot\text{COO}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{N}(\text{C}_2\text{H}_5)_2$ . It therefore has in common with the sulphonamides the amino-phenyl radical,  $\text{NH}_2\cdot\text{C}_6\text{H}_4\cdot$ . Skin tests with procaine were made on 14 of the above cases allergic to multiple sulphonamides. Seven gave positive reactions. Four of these were tested with full oral doses of phenazone, which carries the radical  $\text{NH}\cdot\text{C}_6\text{H}_4\cdot$ , but none gave any reaction.

A possible case of sensitivity common to both sulphathiazole and arsphenamine, which also contains the amino-phenyl radical, has been reported by Weinstein and Domm (1941).

### Summary

The specificity of the sensitivity in 40 cases allergic to sulphonamide drugs has been investigated.

In 60% the allergy was confined to one sulphonamide drug. In 40% it occurred to multiple sulphonamides and to sulphanilic acid.

In about half of the latter allergy was to the sulphonamide radical,  $\text{NH}_2\cdot\text{C}_6\text{H}_4\cdot\text{SO}_2\cdot$ . In the other half it was to the amino-phenyl radical,  $\text{NH}_2\cdot\text{C}_6\text{H}_4\cdot$ , reactions also occurring to procaine.

No cases were seen in which the sensitization was to still smaller groups than these.

I wish to thank the Commanding Officer, 1 N.Z. General Hospital, and the staff of the hospital, for the facilities and assistance in carrying out this work; and the Director of Medical Services, 2 N.Z.E.F., for permission to publish this report.

## TREATMENT OF PULP INFECTION OF THE FINGERS IN THE FIELD

BY

T. DENNESS, M.B., B.S.

Major, I.M.S.

The following is based on observations made after three years in casualty clearing stations, during which time a large number of these cases have been treated. The main object of treatment was to avoid evacuation to the base, and to return the patient as soon as possible to his unit.

There is little need to labour the disability caused by a stiff and painful finger, especially if it be the index finger of the right hand. The finger may be merely useless or, as often happens, an actual hindrance, interfering with the use of the whole hand. It is not proposed to discuss the aetiology at length. Septic cuts, scratches, and unnoticed pricks are probably the chief precipitating causes. Contributory are the difficulties of ensuring asepsis by reason of water shortage,

dust, and the nature of the man's work; this is particularly so in the case of small parties.

Pathologically the lesion is at first a simple pulp infection, though lymphangitis, lymphadenitis, and general symptoms are not slow in supervening; untreated or inadequately treated bone necrosis follows with depressing frequency, with its consequent increase in the period of disability. The symptoms of the established case need little description. Severe and throbbing pain and complete loss of function are the salient features. General symptoms may be fairly severe, with headache and pyrexia; the finger is tense, red, and extremely tender. Here it may not be out of place to emphasize that the utmost gentleness in examination is essential. The patient will have to be re-educated in the use of the finger and hand: the more pain he suffers, the longer this is going to take.

### Management of Cases in Detail

The successful management of these cases calls for attention to detail: a man may be off duty longer with a whitlow than after appendicectomy. In my experience, conservative methods are unavailing; the sulphonamide drugs are useful, but they will not cure the patient without surgical treatment. The primary stage in the treatment is the establishment of adequate relief of tension, and that as soon as possible. "Waiting for pus to form" is mentioned only to be condemned.

The operation is simplicity itself, and I have done many in field ambulance dressing stations with entirely satisfactory results. The anaesthetic of choice is pentothal sodium or some other intravenous barbiturate. If possible, this is preceded by morphine gr. 1/4 and hyoscine gr. 1/150. Adequate drainage is secured by laterally placed bilateral incisions, the pulp space is freely opened with fine Spencer Wells forceps, and a piece of glove rubber drain put across. The incision should not, and need not, traverse the flexure creases of the finger. For infections in the terminal phalangeal area it is, I think, not necessary to carry the incision in an acute case right across the tip of the finger. The drain is taken out after 48 hours; gauze and thick rubber drain are inferior to glove rubber in every way.

The incision of the whitlow is by no means the end of the case from a surgical standpoint. Morphine should, I consider, not be withheld for the first two nights, as a transient increase in the swelling may follow the incision. The incision is dressed once daily with hypertonic saline: Lieut.-Col. P. D. Johnson has suggested the use of sterile 12% sodium sulphate, and in my personal experience this is excellent. Every three hours warm sterile solution is poured over the dressing, which is undisturbed. Heat by means of a hot bottle or, if available, an electrically heated blanket is applied continuously for the first three or four days. I am not convinced that the sulphonamides greatly influence the condition, for after drainage the lymphatic and general conditions rapidly subside.

As soon as the incisions are clean, and swelling is subsiding, the encouragement of active movements should be begun. At no time should any attempt to force movement be made: it merely brings home to the patient that his finger is painful and useless. Progress is neither rapid nor spectacular. When incisions are healed the whole hand is placed in warm water and active movements persisted in. Passive movement is the worst form of interference. The man must be given to understand that further progress depends upon himself. This is the most difficult and trying part of all: it may take up to three months to secure full return of function. This time can be spent usually in the man's unit, supervised by his medical officer.

### Summary

This paper on pulp infection of the fingers has been written largely from the military standpoint.

Emphasis has been laid on early, adequate, but not mutilating incisions to secure relief of tension.

Incisions are not to be made primarily to "find pus" but to prevent phalangeal necrosis by relieving pulp-space tension. Reliance should not be placed on the sulphonamide drugs as substitutes for incision.

Prolonged soaking of the finger should be avoided, and a method of avoiding this is suggested.

Active movements should be encouraged and all attempts at passive forcing should be avoided.

Extreme gentleness in handling is at all times necessary in order to avoid psychological trauma as well as physical discomfort. A case which has been dealt with at the field ambulance is more comfortably evacuated to the C.C.S. than the patient upon whom no operation has been performed. The equipment necessary is found in every field ambulance and C.C.S.

In the presence of general symptoms it is a wise precaution to take a blood film in malarial areas. It is illuminating to note how often an attack of malaria is initiated by the whitlow.

I wish to thank Lieut.-Col. P. D. Johnson, R.A.M.C., for permission to write these notes and also for help given and suggestions made.

## EARLY OPERATION FOR VOLKMANN'S ISCHAEMIC CONTRACTURE

BY

G. A. POLLOCK, M.S., F.R.C.S.E., F.A.C.S., D.P.H.

Surgeon, Emergency Medical Service

The recognition and adequate treatment of Volkmann's ischaemic contracture in its early stages will result in a good functional recovery in most cases. Failure to appreciate the significance of the early developing signs of this lesion is, unfortunately, the cause of much subsequent disability and, not seldom, of even gross crippling deformity.

In a recent standard textbook on orthopaedic surgery, in a paragraph dealing with the question of operations designed to relieve intrinsic pressure on the vessels in the developing stages of Volkmann's deformity, it is stated that "as a rule damage is already irreparable when the arm is observed, and for this reason the operation is seldom applicable." Too complete an acceptance of this ruling will result in many cases progressing to ischaemic deformity which would otherwise have been prevented had the benefits of early surgery been sought. I believe that operative exploration is indicated if arterial damage is suspected, or where gross swelling of the forearm is associated with beginning contracture of the fingers which has not responded to routine treatment. The case history given below demonstrates the good results which do follow surgery in the early stages:

### Case History

While on Army manoeuvres on Dec. 4, 1943, the patient, a well-developed man of 24, was hit accidentally by fragments from a ricocheting bullet. He felt an immediate burning sensation in the left forearm. A first-aid dressing was applied and the patient was admitted to an E.M.S. hospital.

When examined in the hospital four hours after the injury several small wounds were seen on the flexor aspect of the proximal third of the left forearm. There had been very little bleeding. Flexion and extension of the elbow were full and painless, but supination and pronation were reduced by 50% and were accompanied by pain. The fingers were slightly flexed, but could be extended at the metacarpophalangeal joints. There was no loss of sensation in the hand or forearm, and the radial pulse was easily palpable. Prophylactic doses of anti-gas-gangrene serum and antitetanic serum were given, and the administration of sulphapyridine was begun. The forearm was suspended from a Balkan frame to assist in venous return.

Three days after admission the range of movement of his fingers had increased, but there was a tendency to flex the wrist before full extension of the fingers was secured. Twelve days after admission to hospital four small pieces of metal were removed from the forearm under local anaesthesia. Following this minor procedure, the patient experienced an aggravation of pain in his arm and the degree of contracture of his fingers was found to have increased.

When seen on Dec. 24—20 days after injury—the muscles of the proximal part of the forearm were found to be hard, and the patient could not extend his fingers at the metacarpophalangeal joints without at the same time flexing the wrist fully. Volkmann's ischaemic contracture was diagnosed and surgical exploration decided upon. This was done through a linear incision on the volar aspect of the proximal third of the left forearm. The skin and fascia were incised, and superficial muscles which appeared normal were separated. When the insertion of the pronator radii teres was elevated and later partially incised, large blood clots welled up into the wound and profuse arterial bleeding occurred. This was found

to arise from a partially lacerated ulnar artery. No arterial spasm was present in either segment. Ligatures were applied above and below the laceration and the vessels divided. The deeper muscles were soft, dark red in colour, and failed to show any sign of contractility on stimulation even when a small section was removed from the flexor digitorum profundus for microscopical study. The divided structures were reunited, the wound closed in layers, and the wrist fixed in hyperextension on a dorsal plaster cast. A small rubber drain was left in for 24 hours.

The stitches were removed at the end of 12 days, when the wound was found to be well healed. There was still, however, slight flexion contracture of the distal phalanges of the index, middle, and ring fingers. Splinting in hyperextension was reapplied and physiotherapy by infra-red rays was begun. On Jan. 19, 1944 (26 days after operation) the patient had recovered full finger and wrist movement.

I am indebted to Col. W. F. Harvey for the following histological report: "The sections showed muscle fibres in various stages of degeneration or necrosis with loss of cross-striation in most cases. There was quite considerable longitudinal striation, although a large number of the muscle cells were amorphous and eosinophil. There was no fibrosis or inflammatory cell reaction. The appearances in these sections suggested the ischaemia analogous to Volkmann's ischaemia, possibly at an early stage before replacement reaction had taken place."

### Comment

(1) In this case I believe a secondary haemorrhage occurred when the foreign bodies were removed. (2) The increasing tension within the forearm deep to the flexor digitorum sublimis caused mechanical contracture of the fingers. (3) Relief of tension with splinting of the fingers in full extension permitted recovery to occur. (4) Without surgical treatment, replacement fibrosis of the necrosed muscle fibres would have "fixed" the existing contracture, and as cicatrization occurred this existing deformity would have become more pronounced.

I have to thank the Medical Superintendent of the hospital for permission to publish this case.

## Medical Memoranda

### Locked Twins

Though not quite as rare as was previously thought, a case of locked twins seems of sufficient interest to merit publication.

#### CASE HISTORY

Mrs. A., a primipara aged 30, expected her first baby on Dec. 22, 1943. I saw her for the first time on Nov. 27, for obstructed labour. During the previous three weeks her pregnancy had been mildly toxæmic; there had been oedema of the legs and abdominal wall, a systolic blood pressure of 150 mm. Hg, but no albuminuria, headaches, or ocular symptoms. Her pelvic measurements were normal. Labour started naturally on Nov. 26, 36 hours before I saw her; six hours previously she had been found to be fully dilated, and for four hours she had been making strenuous efforts to deliver herself.

On examination she was found to be getting tired, though by no means exhausted. On palpating the abdomen one child was thought to be present lying in the left occipito-posterior position. Limbs were felt anteriorly, and one foetal heart only was heard—in the left flank. Palpation was made difficult by the oedema of the abdominal wall. An anaesthetic was then administered; vaginal examination after catheterization revealed that the membranes were intact; these were ruptured, and the hand introduced to confirm the diagnosis of persistent occipito-posterior position. The head, however, was found to be in an occipito-anterior position. To ascertain the cause of non-descent the hand was inserted further into the birth-canal, and it was then found that a second head was lying in the brim of the pelvis, wedged between the head and shoulders of the first child and completely preventing the birth of either. It was found possible to push up the head of the second child about an inch: forceps were then applied to the head of the first child, which was delivered with little difficulty. The second child was then delivered with forceps; it was also in an occipito-anterior position, and delivery was even easier than the first. Very little liquor amnii escaped. There were no lacerations, and a single placenta was expelled ten minutes later. Post-partum haemorrhage was normal in amount. The uniovular boy babies weighed 5 lb. 6 oz. and 5 lb. 2 oz. respectively.

The puerperium was normal, the mother feeding both babies at the breast; their weights on discharge from hospital were both 5 lb. 4 oz. The blood pressure returned to normal, and the oedema subsided during the first few days.

The frequency of locked twins is said to be 1 in 90,000 deliveries—i.e., once in about every 1,000 cases of twin birth. This statement was made by von Braun of Vienna, but in view of the number of cases recorded during the last ten years it seems

that the condition is not quite so uncommon. It is indeed surprising that locking does not occur more often. Oligohydramnios has been observed in many of the recorded cases, and seems the most likely cause: it was undoubtedly present in the case reported above, in view of the fact that, though there were two children weighing over 5 lb. each, the size of the abdomen did not suggest to anyone who saw the case that there might be a twin pregnancy.

I have to thank Dr. A. G. Winter, of Crowborough, for permission to publish this case.

C. A. HORDER, F.R.C.S.,  
Hon. Obstetrical and Gynaecological Surgeon,  
Kent and Sussex Hospital, Tunbridge Wells.

### Latent Fractures of Vertebral Column after Aircraft Crashes

Three cases of fracture of the vertebral column after forced landings of aircraft were observed in a Polish Fighter Squadron within three weeks. Two of the accidents had occurred within a week of one another, and the third ten weeks previously. In each case there had been a latent period, varying from nine days to nine weeks, between the crash and the appearance of symptoms suggestive of fracture.

#### HISTORY OF THREE CASES

**Case 1.**—Flight lieutenant aged 30. Crash-landed on June 22, 1943. Sustained shock and severe cuts of the forehead. C.N.S. normal. Transferred to an E.M.S. hospital immediately after the crash and discharged as cured some weeks later. When on leave on Aug. 29 he felt a sudden pain in the back while digging in a friend's garden. His friend, who was a doctor, sent him for radiography, which revealed a crush fracture of the bodies of D.12 and L.1; this affected particularly the antero-superior border of each vertebra, the total vertebral border being only slightly reduced. This officer stated that he had had backache following the accident; but this had not been severe, and it had been vague in character. He was readmitted to hospital on Sept. 3 and discharged symptom-free on Sept. 29. No further symptoms have been complained of.

**Case 2.**—Flight sergeant aged 23. Forced landing on Sept. 2, 1943, with no visible injuries. Complained of pain in the right shoulder, which was x-rayed on the same day, no bony injury being apparent. There was no backache, and a physical examination revealed nothing abnormal. On Sept. 14 he complained of pain in the lower back, particularly on jumping from his aircraft to the ground. On examination there was some guarding of the lumbar muscles on the left, and he felt slight pain on bending the trunk to the right. Radiography on this date showed: fracture of right inferior articular process of L.5, obliquely upwards and outwards through the base; no displacement or deformity. He was admitted to hospital on Sept. 16 and was discharged symptom-free on Sept. 26. There has been no recurrence of symptoms.

**Case 3.**—Sergeant aged 27. Crash-landed on own aerodrome on Sept. 5, 1943. Had a cut of the head necessitating two sutures, otherwise no apparent disability. Detained in station sick quarters for 24 hours and discharged, after complete medical examination, without complaining of symptoms. On Sept. 14 he complained for the first time of pain in the lower dorsal vertebrae. Radiographs on the same day showed fracture of the inferior tip of the spinous process of D.7, with little displacement, and transverse fracture of the right inferior articular process of L.3, with no displacement. Detained in hospital until Sept. 20. Discharged symptom-free, and has not complained of any symptoms since.

#### COMMENT

All three fractures were anatomically different, although each was caused by a crash landing in the same type of single-engined fighter aircraft. These crash-landings were attended by varying degrees of damage to the aircraft, and by obvious injuries to the pilot varying from no visible injury in Case 2 to severe facial injuries and shock in Case 1. All three cases occurred among Polish personnel, although no specific significance can be attached to this.

A search in the literature has not revealed any similar occurrences. Rocher and Magnan (*Revue d'Orthopédie*, 1938, 25, 694), report three cases of fracture of the vertebral column following crashes of gliders from low altitudes. They state that these fractures are common after glider crashes, being next in order of frequency to those of the legs and the head. Their cases also show three anatomically different fractures, although each of these lesions at once caused symptoms, making a fracture apparent or probable. All three patients likewise made full recovery, only one (where financial compensation was involved) showing any delay in the resolution of symptoms.

It is felt that a number of undetected fractures of the spine may possibly have occurred through crash-landings, and it is hoped that this note may draw attention to their possible occurrence.

Our thanks are due to Wing Cmdr. T. Montgomery for permission to publish this report.

H. S. SAMUEL, B.A., M.R.C.S., L.R.C.P.,  
Squadron Leader, Royal Air Force.  
J. J.—, M.D.Cracow.  
Flight Lieutenant, Polish Air Force.

## Reviews

### FIELD SURGERY

*Forward Surgery in Modern War.* By Major-General W. H. Ogilvie, M.D., F.R.C.S., Hon. F.A.C.S., Hon. F.R.C.S.C., Army Medical Service. (Pp. 96; illustrated. 10s. 6d., plus 3d. postage; 5s. 6d. post free to doctors serving in H.M. Forces.) London: Butterworth and Co., Ltd.

"Field surgery," the author claims, "is the most important branch of military surgery because upon its quality all that follows will depend." With this there can be no argument. The need for a comprehensive work on the subject, based on hard experience in really modern warfare, has been felt for some time. That need has now been met, in the fifth year of war, by Major-General Ogilvie, who was consulting surgeon to the East African Force in 1941-2 and to the Middle East Forces from 1942 to February, 1944. The work, therefore, is an epitome of experience in East Africa, in Abyssinia, in the Western Desert, Libya, and Tunisia.

It is a slim volume, as any volume on field surgery should be, not merely for the pedestrian reason of easy carriage but because such a work should present principles rather than details. The latter, though important, will vary with every campaign, and field surgeons, not to mention administrators, must be adaptable. There is much also to be said for a work which is confined purely to field surgery, except for one chapter entitled "An Outline of Treatment at the Base." A good deal of confusion has been caused by articles, though not those written by men of genuine field experience, in which the advice given does not distinguish clearly or at all between field and base hospital surgery. Surgeons arriving fresh to the field after almost four years of war had much to learn. In the absence of casualties at home—even air-raid casualties are not really comparable—they presumably had taken their cues from published advice. The latter had been copious. Too much of it has been theoretical and "fancy." Yet if the brief papers published in this *Journal* in 1939 are re-read not much exception can be taken to the principles enunciated by men with long first-hand experience in the last war. Most of their observations have stood the test of time, even in a very different type of war, some of them, such as those of Col. J. M. Weddell on the possible drawbacks of air evacuation and on forward operating have been prophetic. But military surgery does not stand still any more than any other art, and its further evolution is here clearly traced.

General Ogilvie's work gives a realistic presentation. There is no forgetfulness that the first object in war is to win battles, that fighting materials must have priority over medical stores, and that surgery must adapt itself to the campaign in hand. Thus, while his advice on the siting and organization of units, on the arrangement of operating theatres, and on the categorization of casualties is clear, it is also elastic. On technical points he not only gives his personal opinions but calls in the wealth of the Middle East Memoranda on Surgery on various subjects. These memoranda, under his own editorship and often authorship, and those of his predecessor in office, Major-General D. C. Monro, not only have been a guide to Middle East surgeons but have been eagerly sought after and prized far and wide as the real substantial surgical advice in modern warfare. Thus we find also included here the advice tendered by specialists with field experience on resuscitation, burns, wound infection, neurosurgery, maxillo-facial surgery, and chest wounds.

What has the Middle East contributed to the art of field surgery that is likely to stand the test of other campaigns in different fields? In organization there have been the establishment of mobile surgical units and their exploitation to suit fluid warfare. Blood transfusion was, of course, making much headway in civilian practice, but its development and organization in the Middle East will surely serve as a model for the future. The employment of the sulphonamides has followed a similar pattern. In actual technical practices there are some changes unlikely soon to be discarded, even in the possible close fighting of future campaigns. Among these there is the undoubted success of the Tobruk plaster for the transportation of the fractured femur patient and the like. There is the

conservative attitude in chest surgery. There are the practices of exteriorization of the injured colon and of almost routine gastric suction in abdominal wounds. Of the last two the former seems to have eliminated the condition of "colon septicæmia" which in the last war characterized the spread of infection to retroperitoneal spaces; the latter has greatly diminished the dangers of the almost inevitable post-operative ileus.

This book makes a timely appearance and cannot but add to the war effort in a large and very special way. Many surgeons new to field work will presumably soon be actively engaged. Without even a preliminary canter on the farthest fringe of a battlefield they will find much that is strange. What the written word can do to remedy the defect of inexperience has been done here. It is a lucid and attractively written work. Above all it bears the hallmarks of authentic knowledge and intimate experience.

### YEARBOOK OF UROLOGY

*The 1943 Year Book of Urology.* By Oswald S. Lowmley, M.D., F.A.C.S. (Pp. 416; illustrated. \$3.00) Chicago: The Year Book Publishers.

Since research in urological problems has been disorganized by the war in a great many countries, few references are made in this edition to urological literature other than that published in the United States. But, the war notwithstanding, there is much to interest the reader in the 1943 yearbook. It contains descriptions of many new techniques in urological surgery. D. M. Davis's new operation for ureteral and uretero-pelvic stricture, which he calls "intubated" ureterotomy, is of great interest. It consists in splitting the strictured ureter longitudinally and wrapping the ribbon so formed round a large-sized catheter, which acts as a splint. Even though the ureter does not cover more than half of the diameter of its splint, a ureteral channel, normal in shape and size, will eventually be formed. To obtain this successful result it is essential that the catheter selected should be as large as will enter the uncut and presumably normal ureter and that it should be left in position for a minimum of three weeks. J. W. Lord, J. H. Eckel, and other researchers have been experimenting in a similar way with vitallium tubes in the ureters of dogs with good results. Another ingenious operation reported in the yearbook is the utilization of fascial strips obtained from the aponeurosis of the external oblique for reinforcing the female urethra in cases of stress incontinence. It sometimes happens that a surgeon is called upon to re-operate on a patient who has previously undergone an unsuccessful plication operation for this condition, and in such cases he often finds that the urethra has been so damaged that it is difficult to repair it. This difficulty can be overcome by the use of fascial strips according to the method suggested by A. H. Aldridge.

The 1943 *Year Book of Urology* is a very satisfactory publication, and supplies an easy method of revising recent advances in this important branch of surgery.

### RADIOLOGY OF BONES AND JOINTS

*The Radiology of Bones and Joints.* By James F. Brailsford, M.D., F.R.C.P. Third edition. (Pp. 440; illustrated. 45s.) London: J. and A. Churchill, 1944.

The third edition of this standard work shows that the war has not restricted Dr. Brailsford's energies. The method of presentation remains unaltered: the first two-thirds describe abnormalities and diseases as they appear in individual bones, and the final third gives general descriptions of bone diseases. The author has kept a close eye on the international literature, and no observation of importance has escaped him. There are well over 1,000 detailed references, and it is obvious that each author's work has been critically analysed before being included in the text. Dr. Brailsford has also carefully followed up many obscure cases for a long period of years and thus has been able to bridge the gaps in previous editions. The result is a considerable increase in the size of the volume, which is now a veritable encyclopædia of bone diseases.

It is not an easy book to read, and some of the descriptive terms must be incomprehensible to most doctors. Comparing the appearance of a march fracture with a plumber's wiped joint is an obvious example. This, however, is the only flaw in an outstanding book which has no parallel in the English language,

and should be kept for reference by every radiologist and hospital department. The illustrations are excellent, and special tribute must be paid to the author for personally compiling a first-class index.

### Notes on Books

No. 23 of *Individual Psychology Medical Pamphlets* is published at 2s. 6d. by the C. W. Daniel Company, 40, Great Russell Street, W.C.1. This collection of papers suffers from the fact that its appearance has been very much delayed, most of the addresses having been delivered to the Medical Society of Individual Psychology early in 1940 before the war had well begun. After a foreword by Sir Walter Langdon-Brown a past chairman reviews the history of the society and its present chairman forecasts a future in which he hopes to see it amalgamate all other medico-psychological societies and found a common journal. A paper by Dr. Sieckel describes how this one-time disciple of Freud has abandoned the sexual theory and admits that war neurosis may be the result of conflict between self-preservation and personal idealism; and it is interesting to note that his experience in the last war convinced him that the severe war neurotic could be cured only by excusing him future front-line service while retaining his self-respect by the fact that it was the doctor who took responsibility for this direction. Drs. Worsley and Barker discuss the approach to the patient, the first from the point of view of the modern common-sense eclectic psychotherapist, and the latter more from a Jungian standpoint. Next follows an excellent article by Dr. Dicks on analysis under hypnosis. He thinks it is useful in research into psychological mechanisms and in the reintegration of hysterics, but disappointing in the treatment of more severe cases. In a recent note he states that three years' further experience has not led to any modification of this view. Dr. Stungo adds a paper which, if rather more vague, comes to much the same conclusion, though he regards this form of therapy as a useful short cut in all forms of analysis.

Prof. JOHN ZAHORSKY assisted by Dr. T. S. ZAHORSKY has revised the popular *Synopsis of Pediatrics* (Henry Kimpton; 22s. 6d.) for a fourth edition. It is, indeed, a tightly compressed handbook in which the practical aspects of treatment are well stressed.

The Oxford University Press has published a shilling pamphlet for the Royal Institute of International Affairs entitled, *A Reading List for Relief Workers*. This bibliography, compiled in co-operation with some of the British voluntary societies most immediately concerned, is based on a selection of books that should prove useful to those who wish to take part in relief work in liberated territories. The publications are grouped under main headings.

Readers of previous editions of the *Year Book of Obstetrics and Gynecology* (Chicago: The Year Book Publishers; \$3.00) will no doubt have ordered their copy of the 1943 publication. Those who are not familiar with the series would be well advised to start the *Year Book* habit right away. It is an excellent method of keeping in touch with recent advances, and the editorial comments by Dr. J. P. GREENHILL are a useful guide to the busy reader. The literature of the year does not always record progress, and when authors advocate practices which would be generally dangerous—as, for example, accouchement forcé or the use of pituitrin in labour—their views are summarized and the dangers are expressed in no uncertain manner. Among the advances of the last year the over-publicized subject of caudal anaesthesia receives considerable prominence, and many readers will agree with the editor that "despite its auspicious start, continuous caudal anaesthesia will not become part of our general obstetric armamentarium." Analgesia and anaesthesia in obstetrics, the Rh factor, hormone therapy in all its manifestations, human fertility, are but a few of the subjects on which useful information is to be found. This book is an excellent investment for the busy practitioner.

A 14th edition of *The Pharmaceutical Pocket Book* has been prepared by the Codex Revision Committee of the Pharmaceutical Society (London: Pharmaceutical Press; 10s., postage 4d.). This work is the lineal descendant of a pocket notebook for students of pharmacy first produced in 1906. In the course of its evolution it has come to serve a twofold purpose: to introduce to students of pharmacy the fundamental principles on which the work of their profession is based, and to give the practising pharmacist a handy reference book. Opportunity has been taken in the present revision to delete sections which are no longer considered useful to the student or pharmacist, and to modify and expand other parts. Among the many changes in the text and tables mentioned in the preface, additions have been made to the Dictionary of Synonyms and Trade Names (which occupies 76 pages) in order to bring the particulars up to date with respect to the B.P. Addenda, B.P.C. Supplements, and new proprietary preparations. The section on food and diet ends with a tabular list of vitamin contents of official preparations.

SATURDAY JUNE 10 1944

## THE MEANING OF "SHOCK"

On the eve of one of the greatest battles in history the medical profession of this country may well desire some clarification of the problem of shock. In our present issue an analysis is presented by Virgil Moon, and with many of his views workers in this field will be in complete agreement. Yet there remains a considerable diversity of experimental evidence or deduction therefrom, and it is worth while to attempt an analysis which will make the problem less confusing to the mind unfamiliar with the technical aspect. Many of the obstacles to clear thinking seem to arise from the use of the single term "shock." Moon points out that "shock" is a syndrome of multiple aetiology, and Lewis<sup>1</sup> has recently reminded us that "diagnosis is a system of more or less accurate guessing, in which the end-point achieved is a name: these names applied to disease come to assume the importance of specific entities, whereas they are for the most part no more than insecure and therefore temporary conceptions." Has the time come to discard this term? "shock" is a disturbance of the circulation, then so is death; and it is as absurd to search for a single cause of the former as of the latter. If the term is retained it might be clearly understood that it represents only a convenient symbol for "low blood pressure associated with haemorrhage, burns, crushing injury, infection, cerebral injury, diabetic coma, coronary thrombosis, packed pulmonary embolism, etc." A telephone message that a casualty has been admitted in "shock" conveys very little; a message that the systolic blood pressure is 55 mm. Hg is a fact on which action can be taken. Authorities now agree that acute reduction of blood volume is of paramount importance in the low-blood-pressure states of casualties: first, because it is the commonest, and, secondly, it is the only cause which can be treated really successfully. They are far less agreed, and indeed are often silent, when it comes to explaining how a reduction in blood volume reduces the blood pressure. The usual explanation given is that diminished venous return causes diminished cardiac output. This explanation is meaningless in a closed elastic system in a steady state, for cardiac output and venous return are equal, and there is no means of telling which is the cart and which the horse.

Other methods of analysis, however, are becoming available. In the experimental animal the following important principle has been extensively used by Wiggers for study of blood-pressure changes: Mean blood pressure = cardiac output  $\times$  total peripheral resistance. In man the methods developed by Cournand and his colleagues<sup>2</sup> allow serial estimation of cardiac output and thus the use

of this formula. The analysis can be carried further, for though total peripheral resistance cannot be measured directly, blood flow through skin, muscle, brain, and possibly kidney can be estimated, so that an indication of the site of arteriolar vasoconstriction or vasodilatation may be obtained. Known factors affecting cardiac output are changes in venous pressure and heart rate, and substances that affect the heart directly. Thus the cause of a low cardiac output can be analysed by suitable physiological tests. For example, if the venous pressure is raised by a transfusion without any corresponding increase in cardiac output, then clearly the heart itself is at fault.

The data obtained by such methods are still scanty. Cournand and his colleagues<sup>3</sup> have published most interesting results in cases with low blood pressure after injury, and further important contributions are to be expected from this group of workers. It is already clear that mechanisms resulting in low blood pressure may be far more complex than the three suggested by Moon. Haemorrhage, for example, causes a steady fall in right auricular pressure and cardiac output, though blood pressure may be maintained, presumably by arteriolar vasoconstriction. The sudden fall of blood pressure which terminates a large venesection in man is apparently due to vasodilatation in muscle arterioles mediated by vasomotor nerves,<sup>4</sup> a reaction which may be identical with Moon's "primary or neurogenic shock." The steady fall in right auricular pressure on bleeding draws attention to reactions in the elastic venous system. If the pressure in the great veins is regarded as depending on the amount of blood in the venous system and the tone or tension of the veins, then it is clear that removal of blood can result in a fall of pressure only so long as venous tone does not increase. Slow changes in venous tone may, however, play an important part in the process of recovery, and may explain the surprisingly low circulating blood volume but normal systolic blood pressure found in a late phase after haemorrhage and in chronic anaemia. There is also the possibility that the sequence—low blood pressure, low cardiac output, low venous pressure—may result not only from a diminished amount of blood but from diminished venous tone.

The treatment of low-blood-pressure states at the present time is simple, for it consists solely of transfusion. Transfusion raises the venous pressure, and it is immaterial in practice whether the consequent rise of blood pressure results mainly from increased cardiac output or decreased arteriolar dilatation. If the blood pressure fails to rise after transfusion then there are three possibilities: first, the transfusion may be insufficient; this can be ruled out by simple clinical observation of the neck veins by the well-known methods described by Lewis, for if transfusion is continued until the veins of the neck show that the venous pressure is above normal, then no more can be expected from this method. Secondly, the heart may fail to increase its output on the raising of venous pressure; and, thirdly, the blood pressure may remain low from diminished peripheral resistance in spite of increasing the cardiac output. On failure of transfusion to raise the blood

<sup>1</sup> Lewis, *Lancet*, 1944, 1, 619.<sup>2</sup> *Proc. Soc. exp. Biol.*, N.Y., 1941, 46, 462.<sup>3</sup> *Surgery*, 1943, 13, 964.<sup>4</sup> Barcroft *et al.*, *Lancet*, 1944, 1, 489.

pressure, attempts may be made to use other agents, such as constrictor substances, digitalis, and oxygen if arterial oxygen saturation is low. Such methods, however, are likely to prove disappointing. For this reason there may be some disagreement with Moon when he decries the need for new facts. In view of species differences, especially those connected with the erect posture, and the far greater ease of making the fundamental circulatory measurements, such new data may well come from controlled observations on man himself.

## A NATIONAL PATHOLOGICAL SERVICE

We print elsewhere in this issue a memorandum, drawn up by a self-constituted group of leading pathologists, on the future of their specialty in a National Health Service. The White Paper, as they point out, has little to say on this aspect of medicine, and the arrangements by which it is to be enabled to play its proper part in an adequate medical service clearly call for consideration. These will not easily be made, for it is well known that present laboratory resources are quite inadequate; not only are they unprovided under the present system of National Health Insurance, but in many parts of the country distant from the larger cities laboratories staffed and equipped to undertake a wide range of pathological investigations do not yet exist. At the same time it is rather easier to visualize a national service for diagnostic pathology than for any other branch of medicine, because two examples of such a service on a limited scale have been in operation ever since the war began. The Emergency Public Health Laboratory Service, devised originally to reinforce existing safeguards against epidemics due to war conditions, has developed into a valuable instrument for organizing field investigations connected with epidemic disease and for encouraging prophylactic immunization, as well as providing greatly improved and extended diagnostic facilities. The system of reference laboratories, to which material for special and unusual investigations can be sent from any part of the country, is a good illustration of what can be achieved only by an organization on a national scale. The Sector system in London and the Home Counties is another example, more restricted geographically but far more inclusive in its scope. The Sector Pathologist, who is usually the pathologist in the principal London medical school in the Sector, is responsible for the staffing and administration of all laboratories in E.M.S. hospitals in his area. These sometimes include a Public Health Laboratory, and always laboratories part of the duties of which is to undertake any investigations required by private practitioners. Thus on occasion pathologists of academic standing who have eschewed private practice for years have been compelled to undertake it by virtue of holding a whole-time post under the Ministry of Health. Other E.M.S. pathologists, while perhaps not so unaccustomed to duties of this kind, have felt that they are thereby competing unfairly with their brethren in independent practice. In these areas, in fact, a national pathological service of a sort is already in being, and nothing but good can be done by stating plainly that some of those now

compelled to work in it will strongly resist any attempt to retain them in such a service after the war. It is obviously wrong that the occupant of a university chair, whose main duties are teaching and research, should be saddled with administrative and other responsibilities extending far and wide beyond the walls of his own institution. Such an imposition must tend ultimately to the appointment of good organizers rather than brilliant academicians, to the great detriment of pathological science in this country.

The keynote of the memorandum on page 790 is co-ordination, and this, it is suggested, could be achieved by pathologists themselves, provided that the administrative structure permits it. There must be three main branches—teaching and research, clinical pathology, and public health bacteriology—requiring separate staffs. The two latter may well be fused in small centres serving a population of 100,000; in large areas they should be distinct, but may with advantage be housed in the same building. The university department which is apparently visualized as the core and centre of an area in a national scheme should retain its academic freedom, and the professors in charge "should take no part in the professional administration of the hospital laboratories in the regions, and while they should be closely associated with pathologists engaged in diagnostic and prophylactic work they should not themselves be responsible for it." These departments should also be "the training centres of sufficient pathologists to supply the needs of the service." The free interchange of professional and technical staff, particularly in hospital laboratories, is thought desirable "in order to encourage efficiency, to prevent isolation, and provide for study leave and sickness." For the wide administrative responsibilities entailed in directing such a service a special type of officer is contemplated, who should preferably hold also a part-time university appointment; this is "a post requiring knowledge, experience, and tact, and should not be held by anyone too junior to command respect or too senior to have lost touch with bench work." A democratic note is struck in the suggestion that a representative committee of regional pathologists should have a voice in his appointment. A committee within each area of the Joint Authority, as forecast in the White Paper, is also suggested, which shall be representative of all the laboratories in the area and advise the authority on pathological matters. Another important recommendation, unconnected with the main theme of the memorandum, concerns the conduct of coroners' necropsies. It is suggested that there should be a small number of laboratories specializing in medico-legal work in its criminal aspects, working in close touch with the Home Office and attached to a university. For necropsies where crime is not in question the services of a senior hospital pathologist should be secured. We agree that the sooner the general practitioner is relieved of this responsibility the better; it is not only irksome to him, but, except in the most straightforward cases, not seldom quite beyond his capacity.

These and other recommendations in this memorandum call for very careful consideration. They furnish by no means a complete scheme, but they indicate the lines on which a national scheme might work without disrupting

this branch of the profession, and without placing new burdens on some of its most valuable members. How the efforts of the three authorities concerned—university, Ministry, and local or regional authority—are actually to be co-ordinated except by the efforts of pathologists themselves the memorandum does not attempt to suggest. What is quite clear is that almost everything remains to be done before pathology can take its place in a national medical service. The more undesirable features of present arrangements have been accepted by those concerned only as a war necessity, and originally with the idea that peace would see a complete restoration of the *status quo ante*. If they are to be perpetuated and extended this must mean rebuilding from the very foundations.

### THE STOMACH IN PERNICIOUS ANAEMIA

When reviewing recent work on the stomach in pernicious anaemia in 1940<sup>1</sup> we expressed the hope that we might be on the verge of far-reaching discoveries in alimentary physiology. This hope has unfortunately been disappointed. The suggestion<sup>2,3</sup> that the anti-anaemic factor might be secreted by the argentaffine cells of the alimentary tract was not supported by Magnus,<sup>4</sup> who found that these cells were often more numerous in pernicious anaemia than in health. Moreover, the pterins, which are the active principles of these cells, have not yet been clearly shown to have haemopoietic activity or to be related to the haematinic factor in liver extracts. Two recent papers do little more than confirm the view that the characteristic alimentary lesion in pernicious anaemia is destruction or atrophy of the secretory epithelium of the fundus and body of the stomach. Cox,<sup>5</sup> like previous authors, found that an outstanding characteristic was the contrast between the notable change in the mucosa of the fundus and body and the relative freedom from abnormalities in the pyloric zone. None of the findings varied consistently with the duration of the disease or the treatment, and they therefore do not support a suggestion by Wallgren<sup>6</sup> that inflammatory changes in the pylorus may have been removed by treatment with liver.

Wallgren found inflammatory exudation and degeneration of the glands in the pylorus in all his patients who had died before the introduction of liver therapy, though Brunner's glands in the duodenum were usually intact. This may be a disagreement about terms rather than findings, for there seems to be a fairly wide physiological range in the amount of infiltration of the interstitium and the degree of branching of the epithelium in the antrum.<sup>7</sup> Moderate degrees of simple atrophy and atrophic gastritis are so common, particularly over the age of 50, that they may almost be regarded as normal age changes. Gasroscopy is not of much value in determining the precise nature of the lesion in pernicious anaemia, for, although atrophic gastritis is characterized by a pale thin mucosa with a network of easily visible blood vessels, the gastroscopist fails in many cases to recognize proved atrophy of the intral mucosa.<sup>8</sup> Nevertheless, there is no doubt, even from Wallgren's own material, that the morbid anatomical lesion in pernicious anaemia may be entirely limited to the body of the stomach. Biochemical studies of the disorder are

still rather contradictory. Examination of the livers of patients dying from cancer of different parts of the stomach suggested that they had least haematinic activity when the antrum was destroyed.<sup>9</sup> On the other hand, the results with desiccated stomach from different parts of the human stomach show that the haematinic activity resides principally in the body, and its situation therefore coincides with that of the anatomical injury.<sup>10</sup> In the pig the findings appear to be the exact reverse of those in man. The most active anti-anaemic preparations are those obtained from the antrum of the stomach.<sup>11,12</sup> On the other hand, while it is not possible to produce pernicious anaemia in the pig, selective resection of the body of the stomach causes complete disappearance of the P.A. factor in its liver. If the cardia is left behind, parenteral treatment with nicotinic acid will restore the P.A. factor in the liver. This has led to the tentative hypothesis that in the pig the fundus brings about the liberation of nicotinic acid from the food and its absorption, and that this substance then, by way of the blood stream, causes the cardia, or possibly the cardia and fundus, to form the active liver principle.<sup>13</sup>

### OEESOPHAGEAL SPEECH

The use of radiotherapy for cancer of the larynx has shown consistent success only in early cases which would be suitable for laryngofissure. In the more advanced cases radiotherapy has proved an uncertain and often a disastrous remedy, so that there is a large residue of cases in which laryngectomy is the only means of securing any reliable result, the effect of irradiation in such cases being a gamble, with the odds heavily weighted against the patient. The operation itself has now a low mortality, with a convalescence that is not distressing, though many still think of the effects as produced under the conditions which prevailed at the end of the last century. It is nevertheless a mutilating operation which must be justified, because it entails the suppression of the normal voice. At first this loss was overcome by a prosthetic apparatus which supplied a sound to replace the lost phonation, and the sound conducted to the mouth by a tube was turned into articulate language by the lips, mouth, and tongue. Many patients still use this artificial larynx, which with practice enables them to talk clearly, audibly, and continuously. A telephone conversation is quite easy. It has long been known, however, that a few patients were able to produce a real voice with the pharynx and oesophagus, something much more than the indistinct vowel-less whisper yielded by attempts at articulation without any phonation.<sup>14</sup> These patients were regarded as lucky freaks of Nature, but a study of the manner in which these persons produce their voice has enabled a large proportion of those who do not acquire the trick spontaneously to be trained in voice production and to acquire a good voice without any prosthetic apparatus. An elaborate study by means of x rays was made by Prof. Burger of a man who was positively able to shout, although rather hoarsely.<sup>15</sup> It was seen in this man that air imprisoned in the stomach and lower oesophagus could be forced out at will by the diaphragm, and this belching produced a sound, which could be transformed into almost normal speech. Both the air bubble in the stomach and the air in the lower oesophagus were controlled by a pseudo-glottis formed at the upper end of the

oesophagus, presumably from the edges of the two inferior constrictors. The pseudo-glottis is situated at the level previously occupied by the cricoid cartilage, and can sometimes be seen with a laryngoscope as two well-defined bands which can be made to vibrate at will. In other cases these bands appear less defined than would be expected from the quality of the voice.

From a surgical point of view the opening made into the pharynx after turning forward the larynx is better closed vertically, with two short prongs to the fork at the upper end, than by a horizontal closure.<sup>16</sup> Gatewood suggests that this vertical closure may also encourage a better functional adaptation of the inferior constrictors to the formation of the pseudo-glottis.<sup>17</sup> McCall has recommended that the necessary voice training should begin several days before the operation, while the larynx is still in place, and has cited some figures to show that the voice is thus regained more quickly and more easily. However, Woods pointed out many years ago that the physical difficulty of the act of belching to order is much less after the larynx has been removed, because the cricoid cartilage is no longer in close contact with the posterior wall of the gullet, and considerable effort is needed to overcome the force with which the cricopharyngeal part of the inferior constrictor normally holds the larynx back.<sup>18</sup> It is doubtful, therefore, if anything is gained by preliminary training, but the services of an expert in voice production are invaluable after healing is complete. The details of this lie within his province, but he can be greatly assisted in his task by not allowing the patient to whisper without attempting to produce a voice. If he speaks only when he attempts to produce a voice he will much sooner acquire the habit of speaking in this unnatural way. He no longer depends for voice production upon air from the lungs but from the oesophagus; consequently the close association between speech and breathing has to be broken, and it is much harder to break this instinctive association if the patient reverts to it by whispering between the acts of pharyngeal phonation.

### REHABILITATION FILMED

"Accident Service," the second medical film produced by the British Council, was recently shown to a medical audience in London at the Curzon Cinema. The film was made at the Mansfield General Hospital and Berry Hill Hall Rehabilitation Centre, which together provide a highly effective machinery for dealing with accidents in the neighbouring coalfields. In the opening scenes the problem of accidents in highly industrialized Britain is briefly stated with the aid of diagrams, and it is shown that coal-mining is the most hazardous of industries. A miner who has been injured by a fall of rock is brought to the surface by his comrades, who are expert first-aiders. He is taken by ambulance to the hospital, where a fractured spine is diagnosed. A plaster cast is applied, and after a week in bed the miner is able to start walking in the ward. Even during this brief period in bed a planned scheme of exercise is instituted, and there is a progressive increase in the range of active movements, including occupational and recreational therapy, until, with the removal of the plaster, the miner is ready for transfer to the rehabilitation centre for the final stages of his treatment. Miners suffering from other injuries are also shown in different stages. The differences in the mechanism and treatment of a fracture and a fracture-dislocation of the spine are vividly depicted by animated diagrams. Another sequence shows the

technique of wound excision with later skin-grafting in a case of compound fracture of the tibia and fibula reduced under direct vision.

These diagrammatic and operating sequences leave little room for doubt about the part films could play in surgical teaching. "Accident Service" provides a powerful argument for the use of the film in medical education, particularly in regard to those subjects which cannot be learnt adequately from the printed or spoken word and are outside the immediate hospital experience of the student. Although the word "rehabilitation" has now won such general acceptance that it is in danger of becoming a political slogan, there are few who could give a convincing definition of it. This film, which shows in some detail the actual working of one of the pioneer rehabilitation centres, succeeds in conveying what it is so difficult to define in words. Rehabilitation is not a method of treatment but a regimen. The fundamental idea behind rehabilitation is at least as old as the Hippocratic writings. Throughout the history of Occidental Medicine there has been a recurrent struggle between the natural followers of Hippocratic Cos and those of Cnidus. Cnidians, ancient and modern, treat the organ or assail the disease. "For Coans, then and now, disease is a dissociation of functional unity of the whole organism: their therapeutics is directed towards re-establishment of functional integrity."<sup>19</sup>

Another reflection prompted by this film is that rehabilitation is limited by the quality of the primary treatment. In other words, good surgery is still indispensable. Sir Alfred Webb-Johnson, in an introductory speech, pointed out that whatever value might justly be placed upon the personal doctor-patient relationship, the film demonstrated that the injured miner must have an accident organization behind him. This impression will have been shared by most of the audience, but they will have been equally impressed by the special skill, experience, and sympathetic understanding of the mind and life of the miner that have been necessary for the creation of the rehabilitation centre depicted. Sir Alfred paid a generous tribute to Mr. E. A. Nicoll, the surgical director of the centre, and said that his work was a credit to British surgery. The additional point may be made that rehabilitation centres such as Mr. Nicoll has evolved over a period of years cannot be created overnight by official circulars, although his work and that of other pioneers in the same field have provided a splendid foundation upon which others may build.

### A MEDICAL NOBEL INSTITUTE IN SWEDEN

The Royal Caroline Institute (Kungl. Karolinska Medico-Kirurgiska Institutet), which is the medical school of Stockholm—the university (Stockholms Högskola) having no medical faculty—and is in charge of the medical Nobel Fund, has decided to build a Medical Nobel Institute for research in the three theoretical disciplines of anatomy, biochemistry, and physiology. The Institute will consist of three departments in one building to be erected in the grounds of the new medical centre at Norrbacka in the north-west region of the city. The biochemical Nobel Institute was founded in 1937 and is directed by Prof. Hugo Theorell. The physiological department will be a neurophysiological research laboratory privately endowed in 1940 for Prof. Ragnar Granit, who will also be in charge of the new institute. The anatomical department will be connected to a new chair in cytological research to be established for Dr. Torbjörn Cypersson.

## PATHOLOGY AND THE NATIONAL HEALTH SERVICE

*A group of pathologists under the chairmanship of Prof. S. P. Bedson, F.R.S., have drawn up the statement printed below on some aspects of pathology in relation to the proposals in the White Paper.*

1. Pathology, except for a brief reference to public health bacteriology and to "laboratory service," is not mentioned in the White Paper, and we feel it is time that constructive proposals regarding the position of pathologists and the part which pathology ought to play in the new medical service should be made by practising pathologists. We have no mandate to speak for our fellows or for any administrative authority, but we have reason to believe that our views accord with those of the majority of our colleagues.

2. We believe that the closest co-ordination between the two main branches of pathology—academic and applied—is essential to a satisfactory pathological service. Nothing should be allowed to split the component parts into a number of watertight compartments.

3. Academic pathology, mainly concerned with teaching and research, will inevitably be centred in the medical departments of the universities, and will, we suppose, be fully considered in the report of the Interdepartmental Committee. It would, however, be undesirable were research and teaching to be confined to university departments and research institutions. The efficiency of laboratories chiefly concerned with routine work can be ensured only if their staffs have opportunity for independent investigations, and for benefiting by the stimulus that teaching offers. For this reason the staffing of hospital laboratories must be adequate enough to afford the pathologists time to make use of these opportunities as they arise.

4. It may prove expedient, at any rate for the time being, to place what is called public health bacteriology under a separate administration. Whilst we should regret this, we believe that the detrimental effect on pathology as a whole which such a schism would entail could be mitigated to a considerable extent if adequate co-ordination with the rest of pathology could still be maintained.

5. Clinical pathology is an important part of a general hospital service, and as such must be closely bound up with the general scheme of hospital management. But a brief consideration of the technical practices of clinical pathology and public health bacteriology shows that they are so closely related as to make division unprofitable.

6. The co-operation of the two main branches of pathology may be seriously handicapped by being administered by three different organizations—university, Ministry, and local or regional authority. The desired co-ordination of the parts into one whole, however, can be achieved primarily by the pathologists themselves, provided that the scheme of administration is such as to permit of this.

7. Within the areas of the Joint Authority as envisaged in the White Paper there should be pathological committees capable of advising the Joint Authority on all pathological matters. These committees should be representative of all the laboratories in the area, and constituted in a similar manner to those which are already working satisfactorily in some of the defence regions.

8. The university departments of pathology should retain their primary functions of teaching and research, and act as the training centres of sufficient pathologists to supply the needs of the service. The professors should act as the friends and advisers of all pathologists in their regions, and, in some cases, as national advisers on special subjects and research problems. They would take no part in the professional administration of the hospital laboratories in the regions, and while they should be closely associated with pathologists engaged in diagnostic and prophylactic work they should not themselves be responsible for it.

9. The pathologist in charge of the clinical laboratory at the university hospital should, together with appropriate members of his staff, hold university appointments and take some part in the teaching of pathology: he would not ordinarily be

responsible for the clinical pathology from outside hospitals or general practitioners. Such matters as interchange of staff between the university departments and the regional laboratories, the recognition by the university of senior pathologists in the region, and the extension of consultant and laboratory facilities to them would be a matter for detailed arrangement with each university. Several of the provincial universities have already made such arrangements.

10. The public health bacteriological service can only function as a separate administration at its main centres, and even there it must be closely associated with the universities and the larger hospital laboratories, if only to avoid uneconomic duplications of laboratories and staffs. At the periphery there must be complete fusion. A town serving an area containing less than 100,000 inhabitants cannot support more than one laboratory with reasonable economy and efficiency. In larger towns both the hospital and public health laboratories should be housed under the same roof even though under separate administration. There should also be laboratories solely devoted to public health and sufficient in number to provide for field work and epidemiological control throughout the country. In our opinion the population covered by such a laboratory would be from 3 to 4 millions. Provided that the hospital pathologist keeps the public health centre fully informed of all events appertaining to epidemic disease there is no need for any greater divorce of public health bacteriology from hospital pathology.

11. Similarly there should be a small number of laboratories specializing in medico-legal work in its criminal aspects, working in close touch with the Home Office and attached to a university. The majority of coroners' cases are not concerned with criminal action, and should be referred to senior hospital pathologists, but not to general practitioners.

12. The clinical laboratories must be situated in hospitals, under the disciplinary and financial, but not professional, administration of the owning authorities. The remarkable diversity of arrangements under which a professional man may now act as pathologist to a hospital should be brought to an end. The pathologist in charge should be of consultant rank, appointed on precisely the same terms and at the same rate of pay as his clinical colleagues, and serving with them on the medical council of the hospital.

13. Laboratory facilities must be freely at the disposal of the general practitioners in the area, but there should be no isolated small laboratories staffed only by technicians or a solitary pathologist: small laboratories should be under the surveillance of a large hospital laboratory in the vicinity which would provide the staffing. This would ensure a continuous linkage between the rural practitioner desiring pathologist assistance and the research laboratory in the university, without imposing an undue burden of technical or administrative responsibility on any single link.

14. Professional co-ordination of all laboratory services within a university region is necessary for smooth working, and experience in the Emergency Medical Service has shown that this cannot in normal times be the function of a professor or of the full-time director of a laboratory. The person responsible has to act as an intermediary between the pathologist and the administration, making it his business to see that every pathologist has all possible facilities and acting as adviser to the administration. It is a post requiring knowledge, experience, and tact, and should not be held by anyone too junior to command respect or too senior to have *lost touch with bench work*. Such an individual might well hold a part-time post in a university department, and a representative committee of the regional pathologists should properly have a voice in his or her selection. We regard a post of this sort as essential to a proper co-ordination of the service.

15. The hospital laboratories at present in existence have provided only a skeleton service for the country, and a larger number will be needed to provide for the needs of mental hospitals, fever hospitals, and sanatoria, as well as general hospitals.

16. It is in hospital pathology in particular that a free interchange of professional and technical staff is essential, both within a large region and outside it, in order to encourage

# ANETHAINE LOCAL ANAESTHETIC

● 'Anethaine' is a local anaesthetic with unusual and valuable properties, and is used in all forms of local anaesthesia.

In the effective dosage, the margin of safety is high. It has from 10-18 times more anaesthetic activity than procaine and is used in correspondingly lower concentrations.

Complete anaesthetic effect is of long duration, lasting from  $1\frac{1}{2}$  to 3 hours.

It has the very important property of high activity on surface application, and is thus the most suitable preparation for the anaesthetization of mucous membrane and wound edges prior to operative procedures or instrumentation, and in ophthalmology.

'Anethaine' is available in various packings for surface, infiltrative and spinal anaesthesia.

## PACKS

Powder	... 1 and 5 grams
Solution 2% (external)	... 25 cc.
Solution tablets	10 x 0.1 gram
Ampoules (Spinal) 1%	6 and 100 x 2cc.
Dry Ampoules (Spinal)	... 6 and 25 x 10 mg.
Dry Ampoules (Spinal)	... 6 and 25 x 20 mg.
Infiltrative (Powder)	... 3 and 25 x 100 mg.

## SEROLOGICAL NOTES, NO. 1

**'WELLCOME'**  
BRAND  
**REFINED TETANUS  
ANTITOXIN**

**PROPHYLACTIC  
USE**

When tetanus antitoxin is used to confer passive immunity, it is imperative that the dose given should be sufficient to protect against heavy infection.

For many years, doses between 1000 and 3000 international units have been regarded as adequate for prophylaxis. Recent experience,\* however, indicates that 3000 units is the minimum prophylactic dose, and that this dose should be doubled or trebled when gross contamination has taken place.

In consequence, it has been decided to withdraw from sale the 1000 units packing of 'Wellcome' brand Refined Tetanus Antitoxin—Globulins. As a further safeguard against the administration of an inadequate prophylactic dose, the issue of Tetanus Antitoxin, 1000 units per c.c., in multiple dose containers will also be discontinued.

Existing stocks of these packings should be used in conformity with current recommendations, *i.e.*, the contents of at least three 1000 unit ampoules, or an equivalent amount from a rubber-capped bottle, should be given as a prophylactic dose.

\* *Monthly Bulletin of the Ministry of Health and the Emergency Public Health Laboratory Service, Vol. 2, October, 1943.*

'Wellcome' brand serological products are prepared at The Wellcome Physiological Research Laboratories and are supplied by

# OPERATIVE PROCEDURE

## SUPRAPUBIC CYSTOSTOMY AND CYSTOTOMY

This is only one of the 100 important plates which make up the book 'OPERATIVE PROCEDURE', already published in America and now offered in this country.

Here is a series of unique illustrations. Several surgeons have assisted in selecting the subjects and advising on the most vital operative stages to be illustrated. Their practice and experience have provided details of the most progressive, up-to-date technique. A book which must prove of the utmost value to surgeons and medical students alike.

PUBLISHED AT 5/-, Royal 8vo, 112 pages, Full cloth bound.  
(All profits from sales will be given to Red Cross & St. John Fund.)

Copies of 'OPERATIVE PROCEDURE' available shortly.

efficiency, to prevent isolation, and provide for study leave and sickness. Local hospital administration will present financial difficulties to this interchange, which are likely to require central adjustment of a kind which has, on the whole, proved sufficiently elastic to solve similar difficulties in the Emergency Medical Service.

17. While the professional freedom of individual pathologists, as of other practitioners, must be maintained, we firmly believe that some factual, and not merely theoretical, central control of the whole service of pathology will have to be exercised if it is to be conceived as one complete section of medical service to the community. If this conception fails to be a matter of Government concern, medicine will, in this important respect, be moving backwards instead of forwards.

## Reports of Societies

### DISINFECTION OF AIR

At a meeting of the Section of Epidemiology and State Medicine of the Royal Society of Medicine held at the National Institute of Medical Research, Hampstead, under the presidency of Sir WELDON DALRYMPLE-CHAMPNEYS, a demonstration was given by Dr. R. B. BOURDILLON and his colleagues, Dr. O. M. Lidwell, Mr. J. E. Lovelock, and Mr. W. F. Raymond, on the study of air-borne bacteria and methods of air disinfection.

Dr. BOURDILLON explained that at the beginning of the war certain workers under Sir Patrick Laidlaw were engaged at the Institute on this study and showed that a number of methods could be used with good effect against the influenza virus. The work was afterwards taken over by Dr. C. H. Andrewes, who later turned his attention to typhus, and only a section of the former team now remained; but he hoped some useful work had been done. Four factors might be said to dominate air disinfection as seen in field trials and in actual practice. The first was the fact that while people were inclined to take an interest in the installation of any new system of air purification the interest was liable to give place to boredom and the system to fall into disuse. The second was that clinical trials were difficult, except in isolated communities, on account of the many sources of respiratory infection, so that there might be little to show for one's labours. The third was that the particles in which they were most interested, as a rule, were virus particles, and the methods available for their detection were not suitable as yet when the particles were scattered in very dilute concentrations in the air of rooms. Finally, air disinfectants were rather "messy" and troublesome, and concentration had to be carefully controlled. The whole subject must be regarded as still in the experimental stage, and it was well to start on a small scale and in places where there was a special reason for such a system. Dr. BOURDILLON placed the methods available in the following order, of preference:

- (1) Good ventilation and avoidance of overcrowding.
- (2) Daylight, whenever conditions permitted. Recent work had shown the value of daylight, even after passing through window glass, in keeping down bacteria.<sup>1</sup>
- (3) Dust control. There was accumulating evidence that dust-borne infection played a very important part.
- (4) Ultra-violet irradiation, which was to be recommended on account of its cleanliness.
- (5) Various chemical methods suitable in special cases.

#### Chemical Methods

The chemical methods included the use of hypochlorous acid gas, of propylene glycol (which had been widely studied in America and to some extent in this country), of triethylene glycol (which was effective only within a narrow range of humidity, and therefore could not be recommended for general use), of resorcinol (which was effective against freshly sprayed moist bacteria, but disappeared from the air rather rapidly, so

that in order to maintain a steady concentration it was necessary to vaporize considerable quantities), and of lactic acid, which he thought might have a future on the ground of its cheapness and the fact that it was effective over a wide range of humidity. The efficiency of all these agents for killing moist bacteria and virus particles freshly sprayed into the air from cultures or from the respiratory tract depended greatly on the relative humidity of the air. Ultra-violet light showed reduced efficiency at relative humidities of over 70%, but increased in efficiency down to at least 40% relative humidity. Propylene glycol required a humidity between 35 and 75% to be of much practical use. Resorcinol and hypochlorous acid became inefficient below 45% relative humidity, but worked well against freshly sprayed moist organisms at 60 to 70% relative humidity (and probably higher values) at normal room temperatures. Lactic acid was effective against organisms freshly sprayed in saliva at humidities from 30 to 80% or more. In concentrations suitable for daily life many of these agents were relatively inefficient against spores and the dried saprophytic organisms found in dust. Hence if Petri plates were exposed in crowded rooms the number of viable organisms collected might be little affected by these agents unless excessive concentrations were used. As most of the organisms thus found were not pathogenic, this apparent failure to kill might be misleading. Tests appeared to show that lactic acid was better than the other agents in this respect. If air disinfection was needed suddenly on a large scale to meet an epidemic or other emergency, the most practicable method was the evolution of hypochlorous acid gas by boiling a solution of bleaching powder in water with an acid phosphate. (A demonstration of this was given.) If a relatively small number of dwellings were to be disinfected, either propylene glycol or ultra-violet light was probably the safest agent, but lactic acid might be worth trial. The reduction of dust by the use of mineral oil on floors of wood or linoleum was simple and economical and seemed to be one of the most important measures now practicable on a large scale.

Air disinfection was easy in the laboratory but troublesome and expensive when used on a large scale, and therefore inferior to good ventilation when this was practicable. The chief problems were the production of adequate quantities of the bactericidal agent, its distribution in tolerably uniform concentration, the securing of suitable humidity in the air, and the high resistance of dry dust-borne organisms.

#### Discussion

In answer to a question whether there was any prospect of evolving a smaller or more compact apparatus for vaporizing lactic acid Dr. BOURDILLON said he hoped that in the future substances would be available which were easier to vaporize than lactic acid; but lactic acid could be used quite cheaply with a hand spray, and it was this he recommended for offices or small buildings. Sir LEONARD ROGERS asked whether anything could be done with the vaccinia virus. Dr. C. H. ANDREWES said it was possible to kill vaccinia in the air with small sprays. Dr. MERVYN GORDON said that vaccinia was very susceptible to permanganate of potash. This substance inhibited vaccinia and smallpox virus within half an hour. The late Andrew Balfour, when faced with a big epidemic of smallpox in the Sudan, controlled the scarring completely by saturating lint with permanganate of potash and applying it to the skin. His idea had been to kill the secondary infection, but what he really did was to inactivate the primary. Permanganate seemed to work in the same way with other viruses—that of poliomyelitis, for example.

In reply to other questions Dr. ANDREWES said that the envelope surrounding dried particles was a very great mystery. Propylene glycol seemed to be singularly inefficient when it came to organisms with dust, but it looked as if lactic acid might be more effective. Questions were asked on the ventilation of railway carriages. Dr. BOURDILLON considered that it would be better to ventilate than to use chemicals for disinfection, since the opportunities for ventilation were unlimited. Dr. J. A. H. BRINCKER asked whether ozone was discredited. Dr. BOURDILLON replied that very careful tests had recently been carried out by Dr. Elford at the Institute on that very point. Ozone was useless as an air disinfectant. In order to get an efficient killing of air-borne bacteria it would be neces-

<sup>1</sup> British Medical Journal, Feb. 19, 1944, p. 245.

sary to have a concentration of ozone which was likely to do more harm than good. He was not speaking of water-borne infection.

One of the demonstrations carried out in the course of the afternoon concerned the effect of lactic acid on air-borne bacteria in a crowded mess-room. With no method of disinfection the number of bacteria-carrying particles per cubic foot rose, on the average of a four-day experiment, during the middle period when the room became crowded, from some 15 to nearly 40, and continued at that level for half an hour, gradually subsiding to the original figure as the room emptied. When lactic acid was used, the number of particles per cubic foot, on the average of a three-day experiment, never rose higher than about 18, and dropped to 12 even while the room continued to be crowded, subsequently falling to about 5. The reduction in the number of bacteria-carrying particles due to the presence of lactic acid was estimated at 69%. The conditions during this experiment were: relative humidity, 49-75%, temperature, 16-21° C.; lactic acid concentration, 0.08-0.11 mg./c.ft. of air.

### DIETARY SURVEYS

A conference of the Nutrition Society was held on May 20 at the London School of Hygiene and Tropical Medicine, with Dr. JOHN HAMMOND, F.R.S., in the chair, for a second discussion on budgetary and dietary surveys of families and individuals. [The earlier discussion was reported in these columns on March 18, p. 401.]

#### Difficulties of Assessing Intake

Miss E. M. WIDDOWSON and Dr. R. A. McCANCE, of Cambridge, explained their methods and difficulties in conducting individual dietary surveys. They insisted that in the collection of data all food items should be weighed before being eaten, and doubted the accuracy of the "budgetary" and "questionnaire" methods. Individuals should be studied rather than families in view of the inaccuracy involved in converting data for women and children into "man values." Food consumption varied widely even in individuals of the same age and sex. Thus the individual daily food intakes of a group of 14-year-old girls lay between 1,708 and 3,736 calories. A further complication in the use of "man values" arose from the irregular variation of the intake of various nutrients with age. It was true that the protein intake increased fairly smoothly from 40 g. for boys and girls at 1 year to 80 g. for girls and 100 g. for boys at 16 years. The calcium intake, on the other hand, remained steady, because the very young, although eating less, drink relatively more milk. The vitamin C consumption might actually fall, because orange juice was given most freely in infancy. Equally formidable difficulties arose in the application of food tables to convert the data collected in terms of foodstuffs into individual nutrients. Investigators had sometimes made the grave error of taking data for uncooked foodstuffs, particularly vegetables, as applying to the cooked article. Calcium intakes could not be calculated accurately from food tables in the London area because of the high calcium content of the water supply. The iron content of foods might be greatly affected by the nature of the cooking utensils. Thus apples cut with a stainless knife and cooked in a glass vessel were found to contain 0.31 mg. of iron per 100 g., while apples cut with an ordinary knife and cooked in an iron vessel contained 6.0 mg. per 100 g.

Prof. V. H. MOTTRAM suggested that in view of the serious criticisms raised by the previous speakers against both the indirect calculation of calorie requirements and the use of "man values," it might be necessary to revert to the calorimeter. Although this instrument was expensive and laborious in use, it might be better to face these objections rather than take quick methods which gave wrong results. Dr. F. C. HAPFOLD reported a survey among students in Leeds, in which mean calorie intakes of 2,609 and 2,640 were found on different occasions. Mr. A. L. BACHARACH emphasized the danger of confusing consumption with requirement. The mere fact that children were given a certain allowance of milk did not imply that they needed it.

#### "Science" of Cooking Vegetables

Dr. GERTRUDE WAGNER, of the Wartime Social Survey, described her extensive investigation into the methods used by housewives throughout the country in cooking vegetables.

### DIETARY SURVEYS

The effect of the methods most commonly used on the destruction of vitamin C was studied at the Dunn Nutrition Laboratory, Cambridge. To avoid loss of vitamin it was important not to have too much cooking water, not to cook too long, and to eat the vegetables soon after they were cooked. Mrs. B. CALLOW pointed out that whereas in America the abundance of citrus fruits left only 50% of the vitamin C requirement to be derived from vegetables, in this country vegetables must provide 80% of our requirement. There was room for improvement in cooking vegetables.

Dr. G. N. JENKINS, Dr. L. W. MAPSON, and Miss M. OLLIVER described the chemical methods they had worked out for the estimation of nutrients in meals collected at canteens in the Cambridge area. The importance of adequate sampling was emphasized, and as a demonstration a complete meal was homogenized in a Waring blender in a matter of seconds. The agreement between values found by analysis and calculated from tables was generally fairly good. Dr. C. P. STEWART, of Edinburgh, considered that chemical analysis was not usually necessary, calculations based on tables being accurate enough for most purposes. He gave, however, a striking example of the loss of vitamin C in the preparation of vegetables for hospital patients. The raw vegetables contained 14-41 mg. per 100 g., when freshly cooked 10-38 mg., and when finally reaching the wards only 0.7-3.6 mg.

#### Success of School Meals

Miss E. M. LANGLEY outlined the activities of the Board of Education in supplying meals for school-children. She recounted how the first steps had been due to charity. Thus in 1862 Victor Hugo supplied forty poor children in Guernsey with meat and wine. Official action might be dated from the Provision of Meals Act in 1906. The dinners then provided were a monotonous repetition of soup or hash, bread, and rice pudding, and cost about 1d. The meals now served in elementary schools were designed to supply about 1,000 of the child's daily requirement of 2,500 calories, and on an average contained 20-25 g. of protein, 30 g. of fat, 2,450 i.u. of vitamin A, 230 i.u. of vitamin B<sub>1</sub>, 54 mg. of vitamin C, 5.7 mg. of iron, and 425 mg. of calcium. One ounce of dried milk was allowed for every meal, which supplied about half the protein requirement. Sliced raw vegetables were given with "conveyed" meals to make good the deficiency in vitamin C. The meals usually cost about 5d., and were varied and attractive. The "Oslo dinner" of milk, brown bread, cheese, salad, and an orange was popular with children, but took a long time to eat. About 1,500,000 children were now fed at school, as compared with 250,000 before the war.

Dr. M. PYKE, of the Ministry of Food, spoke of the food provided by industrial canteens. The total daily intakes at work and at home for various classes of operative were estimated by questioning individuals as to their consumption over the last 24 hours, portions of food of known size being displayed for purposes of comparison when necessary. It was found that as many as six meals a day might be taken when snacks of 200 calories or over were included. For Lancashire women cotton operatives the daily intake was 2,460 calories and for male "mule" spinners 4,030 calories. A typical mid-workers usually took only 630 calories, which was, however, more than the 510 calories they got at home. The proportion of the daily requirement eaten in the canteen depended on the times of shift. Men "knocking off" at 3 p.m. ate only 35% of their daily intake in the canteen, as compared with 55% for men who finished work at 5.30 p.m. More food was eaten in two sandwich meals taken during the shift than in one hot conventional meal with meat and potatoes. Coal-miners did not appreciate a hot meal served at the coal face. Habit might have a big effect on food consumption. Thus much less cheese was eaten by miners in Lancashire and Durham than in other districts.

#### Diet of the Hospital Patient

Dr. A. LYALL reported a survey of hospital diets in Aberdeen. His method was to take an inventory of the food in selected wards. In a general hospital with 500 beds the food officially provided supplied on an average 1,680 calories, being made up of 65 g. of protein, 70 g. of fat, and 183 g. of carbohydrate daily. Food was brought in privately for the patients

to the average extent of 502 calories, making the total daily intake 2,220 calories, which was nearly identical with the estimate of 2,100 calories for the population in general. It was obvious that in the absence of private food supplies the patients would be underfed. In a maternity home the intake was 2,200 calories without private extras, and 2,540 calories with extras. Adequate feeding was essential during confinement, although overfeeding might cause obesity, particularly in multiparae. Good food in a maternity home was desirable, not only for its immediate effect, but for its educational value. In a hospital for chronic diseases the total intake was 2,130 calories.

Miss M. C. BROATCH, of the King Edward's Hospital Fund, suggested that frequent small meals might be better than fewer large meals. In school the time taken over the "Oslo dinner" had the advantage of resting the children. The goal of 1,000 calories for a school dinner seemed to be set too high, and could be reached only by the frequent inclusion of suet puddings. In hospitals monotony must be necessary. Equipment for food buyers and trained cooks were necessary. In all the foodstuffs to which they were entitled. Hospital patients should receive 120 g. of protein daily, including 78 g. of animal protein. In one hospital no bacon, eggs, or butter were purchased. While he would not accuse those responsible of dishonesty, there was obvious room for improvement. The danger of vitamin C deficiency was slight: he had not found a single case of scurvy in 15,000 subjects examined. Dr. G. GRAHAM, of St. Bartholomew's Hospital, however, reported his recent observation of seven cases of scurvy and of hyperkeratosis of the hair follicles. He stressed the importance of vitamin C in wound healing. Prof. J. R. MARRACK spoke of the loss of appetite in workers when changed to night shift, and Miss M. ANDROSS of the inconvenience of large meals to workers operating under cramped conditions.

The last speaker was Prof. MAYNARD, of Cornell University, U.S.A., who expressed his pleasure that his official mission to this country had afforded him an opportunity to be present at the meeting and also to "look in" on the experiment on human vitamin A requirements which was being undertaken by an M.R.C. subcommittee at Sheffield. There was urgent need to convert data on food supplies and requirements into common terms that could be understood in all countries. The National daily requirement of vitamin A was estimated by the Research Council of the U.S.A. as 5,000 i.u. This was intended to apply to a mixture of "preformed" vitamin A and carotene in the proportion in which they were present in most diets, not, as was sometimes assumed in this country, to either vitamin A or carotene considered separately. There was an unfortunate tendency for lease-lend foods to change their nutritional value at least on paper, merely by crossing the nutrition expert to co-ordinate their ideas and link up their terminology, so that food production might be harmonized with food requirements.

#### CONFERENCE OF PHYSIOLOGISTS IN MOSCOW

When Pavlov was still alive his pupils and fellow-workers would meet regularly at his flat, where in an atmosphere of friendliness they would discuss current work, difficult problems, achievements, new theories, and experiments. After the death of the great Russian physiologist the tradition was continued, but no longer in the teacher's home. In large halls Soviet physiologists hold conferences on physiological problems and discuss the heritage of the scientist and his discoveries and achievements in those branches of physiology in which he did pioneer work. The ninth conference was held in 1941; the tenth opened in Moscow on March 29, 1944. In his opening address Academician Orbeli, vice-president of the Academy of Sciences and chairman of the conference, pointed out that these memorial conferences had been in abeyance on account of the war. It had become urgently necessary to evacuate laboratories into the interior. "But," he added, "there is no power on

earth that can stop the onward march of the scientific thought of the Soviet people." In spite of wartime difficulties, research, far from diminishing in scope, has gone ahead into new channels. The war has created new conditions, and scientists are making full use of them. Theoretical physiology is being widely applied to problems of war medicine. The physiological causes of higher nervous activity established by Pavlov have made it possible for his pupils and research works to develop new methods for every variety of wartime trauma. Pavlov himself carried out his experiments chiefly on dogs, but now in wartime the majority of physiologists are making a study of man himself, healthy and sick, chiefly of the effects of war injuries—a study which permits of a more accurate understanding of the mechanism of higher nervous activity and offers a possibility of rendering better aid in healing the wounded.

Fifty papers were read at the conference, seventeen of them devoted to clinical physiological investigations into the effects of wartime trauma and the development of methods for their treatment. Further experimental work in the study of higher nervous activity, problems of the chemical regulation of the nervous system, the physiology and pathology of the sense organs, organism, and the physiology of the sense organs. The first paper was entitled: "New Material concerning the Genesis of Old Age, and Measures for Preventing Premature Senility," written by Maria Petrova, a very close assistant of Pavlov, who spoke of her as quite the most valued and outstanding of his fellow-workers. Petrova remained in Leningrad during the whole of the siege, in spite of her advanced age—she was 70 in April. In Leningrad, or sometimes in the suburb of Koltushy, she continued her experiments on neuroses in dogs. Her paper gave the results of parts of this work. She concluded with these words: "To slow down the process of ageing is possible by intelligent management of one's life. The first principle of this intelligent management is work."

## Correspondence

### Work of M.R.C. Committees

SIR.—Dr. J. M. Alston's letter in your issue of May 27 about the work of committees of the Medical Research Council touches on important questions about which I may perhaps usefully make some factual comments.

The Council do not themselves claim any higher authority for the opinions of their expert committees than that stated by Dr. Alston. In science there can be no official brand of truth, and seldom any finality of judgment. Nevertheless, when it is necessary to take a decision in practical affairs this must be based on what is considered to be the best advice available at the time, although it should be realized that such advice is open to criticism by other competent and informed persons and is subject to review in the light of further knowledge.

The Council would likewise agree with Dr. Alston that their efforts in promoting and co-ordinating research are complementary to independent endeavours and work assisted from other sources. They are certainly far from wishing to exercise any restrictive function, although they must necessarily discriminate when deciding which projects should receive their positive support.

Dr. Alston is of course right in saying that new drugs were tested and evaluated before the Council set up special machinery for the purpose, but some reservations must be made. Before such machinery existed there was frequently real difficulty in securing adequate clinical trial of new remedies, especially those emanating from commercial laboratories, and in other cases the release of new remedies without any organized preliminary test had undesirable consequences. Dr. Alston is unfortunate, moreover, in his three examples of remedies alleged to have been tried without the aid of official machinery. The Medical Research Council were solely responsible for the first trials—and indeed the first production—both of insulin and of liver extract in this country. The Council also arranged clinical trials of concentrated antipneumococcal serum sent to them from America for their scheme. It is true that all these trials, except the later ones on pneumonia, were made before the Council had appointed a standing Therapeutic Trials Committee to assist them in the matter, but the machinery was not otherwise different.—I am, etc.,

EDWARD MELLANBY.

Medical Research Council.

### Aerial Convection from Smallpox Hospitals.

SIR,—The article by Dr. Killick Millard (May 6, p. 628) and the letter from Prof. Picken (May 20, p. 699) raise again the difficult question of the aerial transmission of smallpox. In the 1920 Glasgow epidemic, to which Prof. Picken refers, I was unable to assure myself, after consideration of all the relevant facts, to what extent the smallpox hospital, which was then a part of Belvidere Fever Hospital, influenced the incidence round it, and concluded that the problem was left undetermined. In the latter part of the epidemic Robroyston Hospital, in a reasonably isolated situation, admitted smallpox patients, and cases did occur within a mile or two of it. But here again, as Prof. Picken says, it was impossible to exclude other possible sources.

It seemed to me that the first step to be taken was to prevent any possibility of spread from the hospital by members of the staff. Accordingly, it was arranged that the staff, including nurses, maids, and porters, should be recruited from volunteers who would undertake to live continuously in the hospital without the routine outside hours off duty, that their salaries would be increased by 50%, and that they would receive a reasonable holiday after the outbreak terminated or at intervals preceded by careful personal disinfection. This system has worked well. Since it was adopted odd cases of smallpox have been admitted, including the small outbreak in the city two years ago. Although it has not been tested out in a major outbreak, nevertheless it has given a sense of security, and I do not know of any instance where spread from the hospital, directly or indirectly, could be alleged.—I am, etc.,

Public Health Department, Glasgow

A. S. M. MACGREGOR.

SIR,—Dr. Killick Millard's communication is assuredly of practical importance, for, as he says, if aerial convection can be absolved of any notable influence in the spread of smallpox public authorities will be spared much expense and their medical officers great inconvenience.

I cannot, however, think that he has been happy in selecting the Purfleet epidemic of 1901-2 as his main proof of aerial convection. Obviously if Dr. Buchanan in 1904 had to admit that even one man from the hospital ships had visited his sweetheart at Purfleet this completely invalidates the statement in his report, presumably written before this painful discovery, that "in the Purfleet epidemic we have to choose between aerial convection or nothing; there is here no question of infection, direct or mediate, through human intercourse or traffic." And, the bottom being thus knocked out of Dr. Buchanan's report, away goes the striking support that, in Dr. Killick Millard's opinion, it gives to the theory of aerial convection.

At this point I was moved to take down *Infectious Diseases*, by my old teacher and chief, that same Dr. C. B. Ker who opened the debate against aerial convection at the Epidemiological Society's meeting in 1904 mentioned by Dr. Millard, and I turned to the section on smallpox hospitals and aerial convection on page 195. The whole of it should be read, but permit me to quote some sentences which seem to be very pertinent. "What is to be the situation of the smallpox hospital? In an adequately revaccinated community this is absolutely immaterial. In Germany the very existence of such buildings is unnecessary, and stray cases of the disease are nursed in general hospitals with no ill effects." He notes that "hospital influence" is generally recognized, and gives the two theories—aerial convection and human contacts—that are held to account for this influence.

"That infection can, under certain circumstances, be carried by air it would be unreasonable to doubt. . . . It must be remembered, however, that there are more ways of leakage of infection from a smallpox hospital than by air. . . . When the Edinburgh Smallpox Hospital was in the centre of the city it was necessary, not so many years ago, to have practically a cordon of police round its walls to prevent the outside public deliberately coming into contact with the patients. And as regards a certain hospital in England, the M.O.H. found that young men from outside were carrying on illicit amours, not only with the wardmaids, but actually with girls convalescing from smallpox, and that within the hospital precincts. It is said that nowadays such breaches of discipline are impossible. It

is certainly to be hoped so, but who can answer for every member of his staff?"

And after briefly recording the Edinburgh outbreak (given in greater detail by Dr. Millard in his account of the epidemiological debate), he concludes, "It is a somewhat melancholy reflection that it is only the extraordinary attitude of this country towards vaccination which renders this discussion of smallpox hospitals necessary. The whole question should be merely academic. As it is, it is unfortunately most practical." Claude Ker, as all who knew him will agree, was a man of immense sanity and rich in the uncommon virtue of common sense.

One other consideration occurs to me. Human nature is infinitely variable and the possibilities of human contacts multitudinous. Aerial convection should have no variables except the wind. If for three months the Edinburgh City Hospital could have an average of fifty smallpox patients without any evidence of infection having spread from the hospital, and this under local conditions that in England would have been illegal, is not this "negative evidence" very positive evidence indeed?

Few, I suppose, would deny the possibility of aerial convection. The problems are what is its effective range and what is its importance as compared with direct human contacts. It is, as Dr. Killick Millard says, a matter of weighing the evidence; but while sympathizing with his desire to put the matter to the test I share the dislike of Dr. Harries that the *corpora vilia* of the experiment should be the general population of a fever hospital not all protected by recent efficient vaccination. A possible, though, I admit, an unlikely, method of investigation would be in any future epidemic to surround smallpox hospitals with hutments at increasing distances from the hospital as centre, and radiating to the four cardinal points (this to test the influence of the prevailing winds); each hutment to be in a compound surrounded by barbed wire entanglements, and to be occupied by a volunteer corps of adult unvaccinated conscientious objectors.—I am, etc.,

Barrow-in-Furness.

JOHN WARE.

SIR,—I think Dr. Killick Millard's views on the aerial convection of smallpox merit serious consideration by those concerned with public health teaching and practice. The evidence against this possible mode of transmission of smallpox has always lacked complete proof. If the causative organisms of enteric and dysenteric infections can be disseminated in pulverized faeces at long range during military campaigns, why should not the virus of variola, which is known to exist in the desiccated crusts of smallpox lesions, be similarly dispersed? I at any rate intend to continue telling my students about the possibility of this officially unorthodox mode of transmission until absolute proof of its invalidity is forthcoming.—I am, etc.,

Cork Street Fever Hospital, Dublin.

CHRIS. J. MCSWEENEY.

### Types of Diphtheria Infection

SIR,—I read with interest your annotation on misleading names in reference to *C. diphtheriae* (May 6, p. 626), and in view of the interest that this subject has for those engaged in clinical fever work I here give figures not previously published of cases of diphtheria typed by me at Knightswood Hospital, Glasgow, between Oct., 1934, and June, 1936, while acting as senior assistant to Dr. W. Dow, the then medical superintendent.

It was noted at Knightswood Hospital that the death rate for diphtheria, which had been 4.3% in 1933, had altered during the first part of 1934 to 8.2%, and that a more severe type of case was being admitted. It was decided, therefore, to type all cases of clinical diphtheria admitted, and to correlate these types with morbidity and mortality. The following were the results obtained:

Total Number of Cases—414

Type	No. of Cases	Deaths		Cardiac Complications		Paralysis	
		No.	%	No.	%	No.	%
Gravis	129	16	12.4	18	14	25	19.3
Intermediate	203	3	1.4	17	8.1	11	5
Mitis	57	—	—	—	—	1	1.7

(Also 15 atypical strain, 5 mixed. No complications or deaths.)

Classification of cases as regards severity, using the total amounts of serum given as an arbitrary measure, gave the following results:

Severity	Gravis	Intermediate	Mitis
Marked .. ..	33	8	12
Moderate .. ..	27	31	30
Mild .. ..	40	61	58

(Mild, 0-24,000 units. Moderate, 24,000-40,000 units. Marked, 40,000 units and over.)

From the above tables it will be noted that in this series the terms gravis, intermedius, and mitis did fit into the clinical picture, although in mitis infections there was a tendency to overtreat in comparison with the other two groups, bearing out what I have since noted, that in mitis infections the local condition is often out of proportion to the general toxæmia.

In respect of gravis cases it was noted that certain strains did not produce a severe infection, and that these strains were slow in producing the typical sugar and other reactions, including haemolysis, and it was therefore thought that there was perhaps some relationship between the severity of a diphtheritic infection and the causal organism's haemolytic power. In an attempt to correlate these, several strains were tested for haemolytic power, using 5% suspension of human, sheep, guinea-pig, rabbit, ox, and horse corpuscles, also poured plates incorporating these bloods (guinea-pig omitted). Briefly, the conclusions come to were that intermedius strains were non-haemolytic for all corpuscles, that mitis was haemolytic, except for sheep's corpuscles and, in certain instances, ox corpuscles, while gravis could be divided into haemolytic and non-haemolytic strains, the former varying in their ability to cause haemolysis according to the corpuscles used. Gravis organisms, however, isolated from severe infections invariably caused haemolysis of human, rabbit, guinea-pig, and horse corpuscles, and certain of these also caused haemolysis of ox and sheep corpuscles when incorporated in poured plates.

These haemolytic strains appeared to be more virulent for mice than non-haemolytic strains, and the average amount of serum given in such infections was 43,000 units, as against 23,000 for non-haemolytic strains, leaving the impression that the haemolytic power of gravis strains is related in some way to virulence. It would be interesting to know the relationship, if any, between the haemolytic capabilities of gravis strains and their component B production as postulated by O'Meara (*J. Path. Bact.*, 1940, 51, No. 3, 317).

As regards the response of gravis infections to ordinary anti-toxin, one usually found (depending upon the day of illness) that the general toxæmia could be controlled by large doses of intravenous serum, although the local condition might progress for several days after the commencement of treatment. In recent cases one has found that adequate dosage has had to be as high as a total of 500,000 units, given over a period of several days.—I am, etc.,

J. LANDESS HORNE.  
Medical Superintendent

County I.D. Hospital, Strathpeffer.

### Increase in Diarrhoeal Diseases

SIR.—The scourge of infantile diarrhoea, still prevalent in London in the early years of the present century, has been vastly diminished until these war years, campaigns against dirt, "kill that fly," etc., obviously having helped. More recent illustrations of dangers of fly-borne infections come from: (1) a cavalry camp where flies swarmed, and dysentery cases were 30 a day, rapidly reduced to nil by a medical officer who had flies slaughtered; (2) districts where so-called summer sickness prevails—i.e., almost universal mild or severe gastro-enteritis—always worse where hot dry weather and neglect bring swarms of house flies. The few households that escape infection are scrupulously free from fly contact. Culture plates exposed to house flies and incubated gave such illuminating results that local doctors now say, "Yes, fly sickness," when called to "summer sickness" cases, hoping thereby to impress the need for "kill that fly."

Successful breast-feeding is the and the greatest safeguard from infection. Infants should never be weaned in the hottest

summer months. In the severe winter epidemic of infantile enteritis in London a few years ago one home had 11 babies: 4 completely breast-fed escaped infection; 7 on part or whole artificial feeding were infected and 4 of them died.

More widespread successful breast-feeding will be attained when common-sense principles—such as are applied in good dairy farms—are followed. A cow must not be chased round a field all day; must be given enough proper food and abundant water, and must be milked regularly and above all completely. So long as mothers are taught in maternity homes and hospitals to give "10 minutes each side" instead of to make "baby strip first breast before changing to second," so long will many successfully "dry themselves off" in a few weeks. Cows are specially treated to yield quality and quantity at the lowest cost; apply similar principles to human breasts for improved results to both mother and baby.—I am, etc.,

London, W.I.

D. C. LOGAN.

### Osteo-arthritis after Carpal Scaphoid Fracture

SIR.—It appears from the article by Robertson and Wilkins on fracture of the carpal scaphoid, in your issue of May 20 (p. 685), that following non-union a large proportion of the cases, eighteen in all, developed varying degrees of osteo-arthritis, whereas three more were able to return to duty with no signs of arthritic changes. Why this difference? It suggests something in the individuals concerned rather than in the injury itself. Two hypotheses suggest themselves: the first, that a focus of infection was present in the individuals developing arthritis and not in the three who escaped. This explanation will not appeal to those who regard osteo-arthritis as having no infective factor. The second, that the state of the cartilage determined the issue. Some people seem to possess, perhaps by inheritance, a vulnerable form of cartilage, others not so. Subpatellar erosion is easily demonstrable and occurs in all cases of osteo-arthritis, whether the knee-joints are involved or not. It is never found in typical rheumatoid arthritis.

McCombie Young (1939) found that 10% of all recruits showed subpatellar erosion. If vulnerable cartilage and a focus of infection were present this might account for the three severe cases of osteo-arthritis described.

It would be a valuable observation were a note to be made in all cases of carpal fracture of the presence or absence of patellar crepitus and of any obvious focus of infection in the teeth, posterior nares, or throat.—I am, etc.,

London, W.I.

H. WARREN CROWE.

### Man's Essential Dilemma

SIR.—Your welcome notice of my *Conscience and Society* (May 20, p. 691) brings out a number of points in this book which other reviews have missed or elided. May I comment on three of these?

I do hold most firmly that Freud's major errors (whether of fact or of stress) are attributable to his own "obsessive" character, and, further, that it is to "aggressive-obsessional" characters that we owe that emotional leadership which drives us to war. But I also hold and emphasize that modern war would probably not occur if obsessional methods of thinking and feeling did not ultimately spread to normal men and women.

That is hardly a "narrow" conclusion. My doctrine of the universality of human prejudice and our human tendency to fall into obsessional ways of thought under stress of emotion willingly admits the political bias at once of the author and of the reviewer of this book. But no argument of mine would make "all belligerents equally guilty," any more than belief in the universality of human selfishness makes two litigants equally guilty in the eyes of a judge. Between nations, however, the trouble is to find the judge and secure the judgment. That search and attainment are among the main concerns of *Conscience and Society*.

The quotation from my concluding tract for the times: "Ten years after this present war has ceased it will no more matter who 'caused' or who 'won' it than it did ten years after the last one" requires careful reading and also the context: "Politically, mankind will be crushed and burdened

by the problems of an aftermath. Individually, men will have forgotten all but the empty seats at table, the pensions, and occasional fireside memories. What matters about a war to the men and women concerned is the starting, the waging, and the stopping of it. Those and not the 'issues involved' are the realities of our present life." Perhaps that will all read less "curiously" in ten years' time.—I am, etc.,

RANYARD WEST.

### Status of M.R.C.P.s

SIR,—The Royal College of Physicians of London has recently published a report on medical education, and I desire to point out an anomaly and what I believe to be a disadvantage in the work of the College. Members play no part. Members, who hold a high and valuable diploma, have never held a statutory position in their College. I believe it is high time that members should be given a better position in the Royal College of Physicians and a share in its government. They could, if allowed, contribute substantial and valuable material to the work of the College. There are almost exactly a thousand members of over ten years' standing, but all are rigidly excluded from any share in the activities of the College, and under the existing constitution the great majority are permanently excluded.—I am, etc.,

Peterborough.

G. F. WALKER.

### Medical Education: Principles and Method

SIR,—One of the more amusing aspects about the present discussions on medical education is the disgusted contempt with which the teachers seem to regard the average student. It would appear that he is an ignorant, uncultured fellow, hardly fit to be received in educated society, and certainly in no state to profit from the pearls of wisdom which fall from the lips of the teachers. Boys, one expects them to say, were very different in their young days. It rather looks as if science has displaced the unfortunate classics in yet another way; instead of: "Why! the boy can't even compose a decent hexameter!" it is now, "Good heavens! the young nincompoop has no conception of modern philosophical theory!"

Dr. Walshe complains that he has yet to meet a student "who has a clear idea of what is meant by a natural law or how it is defined, and who realizes that all science comes from the meeting of the observational and conceptual orders of experience, . . ." I can well believe it. I doubt whether even Dr. Walshe talked like that at the age of 18 or 20. At that age a boy is learning how to *do* things, not how to talk about them in high-sounding phrases. It is reality he is after, not abstractions; those will come later of themselves if he is of that turn of mind; if he is not, I do not think anything will make him so.

It would, of course, be quite easy to produce students who could recite stuff about conceptual orders of experience *ad lib*. Very nice, too, and most useful training for a philosophical lectureship; but not really of much guidance when it comes to Mrs. So-and-so's urgent post-partum haemorrhage, which is the sort of problem the students are really being trained to tackle. What we must bring ourselves to realize, painful though it may be, is that the great majority of medical students are apprentices to a craft; as G.P.s they will be craftsmen whose job, as Sir Thomas Lewis has pointed out, is to apply what they have been taught according to established principles, not experiment and theorize. You do not expect the man who drives your car to be familiar with Fourier's "Theory of Heat"; you expect him to listen to the engine and tell you whether that funny noise is really a "big-end" gone or just imagination. You do not even expect him to know much about the "general principles of scientific thought." You do hope he is intimately acquainted with the ailments of motor cars and how to cure them.

It may be argued that this is too narrow a view; that even the motor mechanic would be all the better if he were a bit of a scientist as well; as well—not instead. But art is long and life is short. When a practical job has to be done the "how-to-do-it" knowledge is what counts. The reason why, and the reason behind that, and so on in an infinite series, are no help, except in so far as the first few terms may serve as aids to memory. Unfortunately, medicine consists largely of

unrelated facts, and so long as that remains true students will just have to commit these facts to memory as best they can.

Not that I have any wish to belittle science or even its more abstract principles. But I suggest there is some danger of over-estimating their importance in practical medicine. It is apparently possible to be a very efficient doctor with only the crudest notions of elementary physics, for example. I remember a student being asked by an eminent honorary why the mediastinum moves over towards a collapsed lung. The student thought it was due to a pressure difference: the pressure on the sound side pushed it over. "Pressure?" said the honorary. "Pressure has nothing to do with it; it's pulled over by suction!" There was no "come-back" to that one, of course, and the teacher moved serenely on to the next bed, followed by the admiring crowd of students, who would cheerfully have said it was pulled over by the moon if they thought that was what a potential examiner wanted them to say. Quite right too; only a research worker wants to know why; sufficient for the practical man that it is so.

There is another objection to the attempt to teach principles before practice (or another aspect of the objection), and that is that the human mind does not work that way—at least, not if it can help it. You do not try to teach a child the philosophical principles of mathematics before teaching it to add and subtract, although in logic they come first. The results would be sadly disappointing if you did. The facts must be demonstrated and the techniques learnt first; philosophizing comes later. That is what I meant by saying that the pre-clinical student is still learning to *do* things: he is still learning (and re-learning) how to measure, and weigh; and precipitate, and connect batteries to induction coils (lots of them can't do that), and a host of other strange things which in after-years will become second nature. He might be expected to infer something of scientific method from all this, and so, I think, he does, according to his lights and interests. A really good teacher could help him to infer more, but teachers as good as that are born, not made.

The point I am trying to make is that the vision of graduates issuing forth from their medical school equipped with a mature scientific philosophy, not to mention an ability to behave with common sense on all occasions, is a Utopian dream. The real scientific mind is a rarity, and it starts to be one in early childhood. If you spot one, just encourage it and give it scope; it will teach itself. Moreover, if you give it half a chance it will not go into general practice. But the ordinary people, who are going to make ordinary efficient medical craftsmen in time, must be taught their trade by means appropriate to the object they have in view.—I am, etc.,

Brancepeth, Co. Durham.

W. E. HICK.

SIR,—Dr. Walshe seems rather exacting. Why should a clinical clerk know what is meant by "the structure of experience"? The Church implants real grace in the young not by teaching theology but by using perceptual myths. "For effective teaching there must be the disk of really apprehended dogma; rays diversely reflected and refracted from clouded sources will not do." To know "the direction in which to look for light", the student must memorize facts, must be taught to perceive, must do routine techniques, and must be given a framework of crude "Platonic" concepts—such as the textbook diseases and concepts implied by a method of case-taking—to act as his "organs of interpretation" akin to his organs of sense. If at first he imagines given symbols to be adequate reality-references he can be undeceived later.

Minds capable of continued reflection are a minority; the majority want definite snippets of experience. Also generalization of process-likeness is a talent not always found in the man who is apt to discriminate differences in percepts. Often what delights the synthesizing philosophic mind fatigues and irritates the analytic technique-loving mind; often it exasperates the philosopher when the analytic mind confidently applies to a whole his logical deductions from an abstracted past. A doctor who considers all statistical results and all pharmacological tests superior to clinical judgments is no wiser than the man who yells "Equal pay for equal work" and forgets to add "by equal people."

A good teacher saves a student much labour, but students should rightly learn many more facts than they need in practice

routine. It is the physiology that a man has forgotten that enables him to read, e.g., Burridge and Adrian, with some ease, understanding, and profit.—I am, etc.,

Greenford.

W. THOMSON BROWN.

SIR.—Dr. Walshe (May 27, p. 728) rightly emphasizes the necessity for teaching the medical student the principles involved in scientific thought and method. It would be a great help to the development of the student's intellectual powers if he were also taught that these principles could be applied to other problems in life besides medicine. Doctors are too often swayed by emotion rather than guided by reason when discussing non-medical subjects.

Another much-needed reform is the appointment of a general practitioner to the staff of every teaching hospital, for most of the students take up general practice after they have qualified. The idea of a G.P. let loose among students who are being carefully nursed along academic lines appals the average teaching consultant, but there could be no harm in having a G.P. present at a medical round once a week to add to the discussion of the cases.—I am, etc.,

London, W.5.

H. STEPHEN PASMORE.

### Medical Certificates for Special Rations

SIR.—It is with appreciation and relief I see the signs of a small revolution by the Guildford Practitioners' Group (May 20, p. 701) regarding medical certificates for special rations. May I also add my little voice and hope that other practitioners and branches of the B.M.A. will take this matter up.

My main complaint, and it is made with considerable feeling, is the issuing of the following certificates for extra milk and eggs for active tuberculosis of all types and for gastric, duodenal, and anastomotic ulcers. Now, Sir, whether the war lasts another week or another generation these people will still have their gastric ulcers and active tuberculosis, and I fail to see why we should be compelled by the Ministry of Food to issue continuous certificates every three months or less for these patients. Even if their ulcers cause them no more pain, with the present difficulty in getting milk the patients will always ask for their milk certificate, and the doctor must therefore give it to them.

There is also another point against which I should like to see the medical profession protest, and that is the Board of Trade's request for certificates for corsets and brassières. Under present emergency conditions I have no objection, and I am sure that members of the medical profession will agree with me, to the initial certificate requesting the manufacture of the article required. What I do object to is that my obese, viscerotropic, and post-maternity patients, etc., should stand up in front of me while I gaze upon their garment and see whether it fits. I am no corset or brassière expert: I do not know a doctor who is; and, furthermore, if the garment does not fit, then who knows better than the patient? Over the last six months I have refused to sign any certificates stating that the particular garment is to my satisfaction for the complaint for which it is issued. The manufacturers concerned are persistently writing or phoning me, and I am at present awaiting a call from a representative of the Board of Trade.

I feel that the only way in which we can stop this unnecessary waste of time and paper is for individual Branches to make the complaint, and I am sure that if there are enough complaints the B.M.A. will have to do something.—I am, etc.,

Rugby.

T. E. WAINE.

### The Colonial Medical Service

SIR.—To Sir Philip Manson-Bahr's tribute (May 27, p. 732) to the work of members of the Colonial Medical Service, which I heartily endorse, I could add more. But I will only mention two other examples: one that of Dr. J. W. Field, Chief Malaria Officer at the Institute for Medical Research of Malaya (with whom I had the honour to work); and the other that of Dr. Gordon Ryrie, Superintendent of the Leper Settlement at Sungei Buloh, F.M.S. In 1937 Dr. Field refused promotion rather than discontinue his work on the chemoprophylaxis of malaria. Dr. Ryrie's work for the lepers brought out whatever latent happiness a leper colony could enjoy, and

brought such satisfaction to himself that in 1941-2 he preferred to remain under the Japanese invaders rather than escape and leave the colony.

If those diehards of the medical profession who consider that the fee is the only or the main incentive to good work could once free themselves from their chains, perhaps they too would find such satisfaction in their work itself that memories of the "money incentive" would become as a bad dream that is passed.—I am, etc.,

London, W.1.

COLUMBA GUEST.

SIR.—From time to time you print an advertisement for medical officers for the Colonial Medical Service. May I draw attention to two statements in it which are misleading: (1) "There are ample opportunities for work in medical research." (2) "There are large numbers of super-scale posts to which promotion is on merit." Any chance of work in medical research is eliminated by a reduced staff and enormously increased routine clinical pathology and medico-legal work. Promotion is usually on seniority; probably rightly so, as it at least eliminates any sense of favouritism.

I do not wish to put men off the Colonial Medical Service. I think it is good. But I feel they should not apply for a post on the strength of an ingeniously worded advertisement.—I am, etc.,

R. D. REID,  
Pathologist, Gold Coast

## Obituary

SIR CUTHBERT WALLACE, Bt., K.C.M.G., C.B.

Former President, Royal College of Surgeons

Sir Cuthbert Wallace, who died on May 24, served his profession in many high offices, and will be remembered with warm regard and admiration by his colleagues and a host of former pupils.

Cuthbert Sidney Wallace was born in 1869 at Surbiton, Surrey, the son of the Rev. John Wallace. He was educated at Haileybury College, a school in which he continued to take the greatest interest throughout his life, serving for many years on its Council. From Haileybury he went to St. Thomas's Hospital, and qualified in medicine in 1891. His bent was towards obstetrics and surgery, and he became a Fellow of the Royal College of Surgeons of England within two years of his qualification, and in the following year, 1894, M.B., B.S. (London), obtaining the gold medal in obstetric medicine and qualifying for the gold medal in surgery.

St. Thomas's was one of the great interests of his life. He served it as surgeon for many years, and on reaching the age of retirement was elected consulting surgeon. He was also lecturer on surgery in the St.

Thomas's Medical School and afterwards Dean. Both as surgeon and as teacher, and in everything to do with the School, his skill and wisdom and devotion laid it under a great debt, and generations of St. Thomas's men in all parts of the world have occasion to think of him with affection and gratitude. He had also been surgeon to the East London Hospital for Children.

One of the outstanding experiences in his early life was his service in the South African War. In the autumn of 1899 he was asked by his friend Sir Anthony Bowlby (who, like himself, was to become President of the Royal College of Surgeons) to join the Portland Hospital in South Africa, and, Wallace eagerly assenting, they worked together there until the middle of 1900, when the hospital was dismantled. On their

(Lafayette)

return the two surgeons collaborated in producing a small book relating the story of the Portland Hospital. That, however, was only the prelude to a much more exacting and prolonged military experience. During the war of 1914-18 Cuthbert Wallace was attached as consulting surgeon to the First Army of the British Expeditionary Force and eventually became Major-General, A.M.S. Here again he was in close association with Bowlby, who, although working with the Second Army, was attached to headquarters at St. Omer, and had oversight of both First and Second. Wallace's work for the Forces during that war earned him widespread recognition. It was characterized by the thoroughness and care for detail which marked all that he did. He was mentioned in dispatches and received the C.M.G. in 1916 and the C.B. (Military) in 1918, and at the end of the war he was advanced to K.C.M.G. He wrote in collaboration with Sir John Fraser a small volume entitled *Surgery at a Casualty Clearing Station*, embodying the result of their joint experiences in that type of work during several years on the Western Front, and containing much of value for the next generation of war surgeons who came along twenty years later. It was illustrated by many sketches by Lady Fraser. When, in April, 1919, the British Medical Association held a special clinical and scientific meeting to review the medical lessons of the war he acted as joint general secretary.

For very many years Cuthbert Wallace was closely identified with the work of the Royal College of Surgeons of England. He was elected to its Council in 1919 and served until 1935, when he was made President, occupying the chair for three years. He had been a member of the Board of Examiners from 1919 to 1929, Bradshaw Lecturer in 1927, and Hunterian Orator in 1934. Many other useful activities occupied him during the later years of his life when he no longer worked in the operating theatre. Outstanding among them was his directorship of the medical services of Mount Vernon Hospital and the Radium Institute. He was also a member of the Radium Commission. He interested himself greatly in the work of the British Empire Cancer Campaign and was chairman of some of its committees. He served for some time on the Medical Research Council and was a valued member of the Army Advisory Council. His interest in the day-to-day work and difficulties of the profession showed itself in his presidency of the London and Counties Medical Protection Society. He was not content to appear at the annual meetings and make a brief speech, but he attended regularly the council and committee meetings and maintained a real interest in the detailed work of the society. As a chairman he was most businesslike. No time was wasted. The presence in the chair of this quietly efficient and dignified man made everyone feel that they must give of their best.

Sir Cuthbert Wallace's published works include volumes on the war surgery of the abdomen and on prostatic enlargement. He was the author of many contributions to *St. Thomas's Hospital Reports* and the *Transactions* of the Clinical and Pathological Societies. He was also one of the editors of the Surgery Section of Sir William Macpherson's *Medical Services of the War* (1914-18).

He was made a baronet in 1937. He held honorary doctorates of Oxford, Durham, and Birmingham, was an Honorary Fellow of the American Surgical Association, and an Officer of the Legion of Honour. He was also a J.P. for the County of London.

Sir FRANCIS FRASER, Director-General, Emergency Medical Service, writes:

Cuthbert Wallace disliked strongly the idea that he might have to give in before the end of the war. A few days before his death he was planning how he would still be able to help with advice, even though he could no longer attend the conferences at the Ministry of Health. For nearly five years as Consultant Adviser in Surgery to the Emergency Medical Service he served the country well and gave freely from his store of experience of surgery in war and in peace, from his knowledge of men, and from his capacity for wise and balanced judgment. In the earlier years of the war he visited most of the larger hospitals in the South of England and reported on their strong points and their weaknesses and the part each should play in the Emergency Scheme. Nothing he said was taken

amiss: it was so honest and so clearly helpful. The difficulties and discomforts of travelling kept him at home for the past year or more, and it was as Chairman of the Consultant Advisers that he was able to continue to help so well. Many problems arise when civilian hospitals and civilian doctors are required to deal with Service patients, and the more difficult of these were kept for discussion with Wallace. It is not, however, for his help in solving administrative difficulties that we at the headquarters of the E.M.S. owe so much to him. It is for his loyal support at all times, for his gentleness, for his friendliness, and for the atmosphere of goodness that he brought with him.

Major-General Sir ERNEST COWELL, K.B.E., C.B., D.S.O., writes:

May I add my tribute to the honoured and beloved memory of Sir Cuthbert S. Wallace. As surgical specialist to 23 C.C.S. and later O.C. 1 C.C.S. in France 1915-19 I came into intimate contact with Sir Cuthbert, who was Consulting Surgeon to the First Army. His advice and judgment were sound and always helpful. He never issued surgical directives but rather "suggestions," explaining the general idea and leaving details to the individual surgeon. His work on military abdominal surgery will be remembered, and his dictum, "The surgeon who does not trust the peritoneum is not fit to do abdominals," is still true to-day. Sir Cuthbert was an ideal Army surgeon, unselfish, devoted, courteous, and thoughtful. His name deserves undying fame.

By the death of Dr. ROWLAND HAMER at Ashton-under-Lyne on May 25, in his 70th year, the area has lost a physician who, by his original and striking personality, had earned the respect and warm regard of all his colleagues and the gratitude of many patients. He combined practical sympathy for the more needy of his clients with a sound clinical judgment, and leaves behind a well-deserved reputation as a doctor of the old school. He graduated M.B., Ch.B. at Manchester in 1899, served in France and Belgium during the last war, and had held office as a member of the Ashton-under-Lyne Town Council.

The following well-known medical men have died abroad: Dr. R. O. Rosenberger, professor of immunology and bacteriology at the Medical College of Philadelphia, aged 64; Gen. Med. Rat. Prof. Carl Jacoby, emeritus professor of pharmacology at Tübingen and one of Schmiedeberg's pupils, aged 87; Prof. Alfred Kleinknecht, for many years leading surgeon at Mulhausen, Alsace, aged 73.

## Universities and Colleges

### UNIVERSITY OF EDINBURGH

Sir John Fraser, Bt., K.C.V.O., honorary surgeon in Scotland to H.M. the King and regius professor of clinical surgery in the University, has been elected by the curators of Edinburgh University to the office of Principal, and will take up the duties of that post on Oct. 1.

### ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

Mr. Norman M. Dott, F.R.C.S.Ed., will deliver a Morison Lecture in the Hall of the Royal College of Physicians, 9, Queen Street, Edinburgh, on Friday, June 23, at 5 o'clock on "Experiences in Neuropsychiatry, Edinburgh, 1940-4."

## The Services

Temp. Surg. Lieut. T. Haw, R.N.V.R., has been mentioned in dispatches. This name appears in a list of awards for outstanding courage, determination, or devotion to duty in certain of H.M. ships in successfully escorting convoys to North Russia in the face of attacks from enemy submarines and aircraft.

### CASUALTIES IN THE MEDICAL SERVICES

*Died of wounds in Italy.*—Capt. G. E. Yardley, R.A.M.C.  
*Killed.*—War Subs. Capt. N. W. Jones, Temp. Major R. Stuppel, R.A.M.C.  
*Wounded.*—Temp. Major G. S. Ferraby; War Subs. Capt. A. P. D. Montgomery, C. P. Silver, and A. Wattison, R.A.M.C.

## A 'Hall-mark' for Vitamins

A recent Government decision will go far to give to vitamin foods the status which the hallmark gives to gold. The Ministry of Food is issuing regulations under which it is intended that foods claiming to contain vitamins must bear on the label a quantitative disclosure of these active ingredients.

This move should put an end to unsubstantiated claims that this or that food "contains vitamins." Doctors will look for the 'hallmark'—the disclosure on the packet. If the 'hallmark' is missing, they will draw their own conclusions, as they would about unstamped gold.

### THE CASE OF BEMAX

Vitamins Ltd., proprietors of Bemax, warmly approve the Government decision. For years they have preached vitamin disclosure; even more, they have practised it. Every statement as to the vitamin content of Bemax has been supported by publication, on each package, of a quantitative analysis.

1 oz. of BEMAX supplies, at time of manufacture, approximately:

Vitamin A	280 i.u.	Manganese	4.0 mg.
Vitamin B <sub>1</sub>	240-420 i.u.	Iron	2.7 mg.
Vitamin B <sub>2</sub> (riboflavin)		Copper	0.45 mg.
	0.3 mg.	Protein	33%
P.P. factor	1.7 mg.	Avail. Carbohydrate	39%
Vitamin B <sub>6</sub>	0.45 mg.	Fibre	2%
Vitamin E	8 mg.	Caloric Value	104

### DISTRIBUTION OF AVAILABLE SUPPLIES

The appropriate Ministries have asked that Bemax should be reserved for those taking it on medical advice.

Priority is accorded to hospitals, Public Health Authorities, clinics, doctors and the Red Cross.

Direct orders from members of the medical

profession will, as heretofore, be given priority. Supplies cannot, however, be forwarded direct to patients.

There is no formal rationing scheme for the public but chemists are co-operating with us to secure equitable distribution.

*Vitamins Ltd., 23, Upper Mall, London, W.6.*

## PRICE REDUCTION

**'Thiazamide'** (Sulphathiazole)

TRADE MARK

BRAND

introduced as **'M & B 760'**

Demands for both Service and Civilian requirements are being fulfilled. Output now enables us to offer substantial price reductions; effective as from June 12th. (Particulars available on application).

### SUPPLIES:—

Tablets 0.5 Gm. - - Containers of 25 and 100  
Powder - - - - Containers of 15 Gm.  
Ampoules of soluble salt - Boxes of 6 x 1 Gm.

Obtainable through the usual sources of supply.

Manufactured by  
**MAY & BAKER LTD.**

Distributors  
**PHARMACEUTICAL SPECIALITIES (MAY & BAKER) LTD., DAGENHAM**

The April number of the *Bulletin* of the National Association for the Prevention of Tuberculosis (Tavistock House North, Tavistock square, W.C.1) announces that the N.A.P.T. is to undertake a comprehensive investigation into the psychology of tuberculosis, to last the first place for some twelve months. All types of patients with pulmonary tuberculosis will be studied. The work will be carried out by a competent psychiatrist with an assistant psychiatric social worker. Full personality studies will form the basis of the work.

The Minister of Health has been in consultation with the Minister of Labour and National Service and the Minister of Pensions about questions which arise in connexion with the placing in suitable employment of persons suffering from some form of psychoneurosis or psychosis. Such persons often break down in the employment in which they have been placed and the Minister of Labour has experienced difficulty in finding them work which they can usefully perform. The Ministry of Labour and National Service consider that the advice of a skilled psychiatrist would be most helpful to officers at Employment Exchanges in determining whether a worker known to be suffering from psychoneurosis or psychosis whom it has hitherto been difficult to place in industry is, in fact, suitable for employment and, if so, what type of employment he or she is best fitted to undertake. Arrangements have accordingly been agreed between the Departments concerned.

The York Clinic for Psychological Medicine at Guy's Hospital, after serving some of the general needs of the hospital since the 'blitz' of 1940-1, has now been opened for its original purpose. Thirty of the forty-three beds are reserved by the Emergency Medical Service for psychiatric casualties among officers of each of the Services; the remainder are available for civilians. The acting medical director is Dr. Felix Brown and the sister-in-charge is Miss E. Purcell.

## EPIDEMIOLOGICAL NOTES

### Discussion of Table

In *England and Wales* notifications of measles, acute pneumonia, and whooping-cough exceeded those of the previous week by 123, 102, and 71 respectively, but those of scarlet fever were lower by 58.

Lancashire reported a decrease of 71, and Yorks West Riding 17, in the notifications of scarlet fever, the total for pneumonia, however, going up by 23 in the latter county. The incidence of whooping-cough rose in Kent and Middlesex by 48 and 35 respectively. Essex reported 48 more cases of measles, than last week, but in contrast to the general trend Kent reported 59 cases fewer, and Durham 53. The incidence of diphtheria in Lancashire and Yorks West Riding remains relatively high, one-third of the total cases for the country being notified in these counties during the week.

Dysentery is still prevalent, and 276 cases (4 fewer than in the preceding week) were recorded. The largest of the new outbreaks was Yorks East Riding, Bridlington M.B. 37. The other principal centres of infection were Lancashire 53, Kent 24, London 18, Northamptonshire 17, Southampton 13, Derbyshire 13, Warwickshire 12.

In *Scotland* notifications for measles were 81 fewer than last week, scarlet fever 27, and diphtheria 23, but the total for dysentery rose by 27. The 138 cases of diphtheria were the fewest reported for five months. The largest returns for dysentery were Edinburgh 21, Lanark County 17, and Glasgow 10.

In *Eire* the only change in the trend of infectious disease was an increase of 50 in the notifications of measles, almost one-third of the total being notified in Dublin C.B. A case of typhus was reported from Roscommon, Castlereagh R.D.

In *Northern Ireland* there were 22 more cases of diphtheria than last week, almost half the total being notified in Londonderry C.B. Slightly more than half the cases of scarlet fever were notified in Belfast C.B.

### Week Ending May 27

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,853, whooping-cough 2,427, diphtheria 507, measles 2,662, acute pneumonia 774, cerebrospinal fever 57, dysentery 274, paratyphoid 4, typhoid 9.

### Eire: Births and Deaths Week Ending May 13

The figures for births and deaths for Eire were not received in time for publication in the general table. The figures were: births 593, deaths 222, deaths 0-1 year 29; death rate 14.4; deaths from paratyphoid (B) 1; scarlet fever 0; whooping-cough 0; diphtheria 1; measles 2; diarrhoea 8; influenza 1; pneumonia 9.

No. 23

## INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended May 20.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1944					1943 (Corresponding Week)

### ANY QUESTIONS?

#### Tobacco, Alcohol, and Hypertension

**Q.**—What part, if any, is played by tobacco and alcohol in the production or maintenance of so-called essential hypertension? Many intelligent patients with this condition, and otherwise fit, have asked me what are the scientific reasons that prompt me to advise them to abstain from these drugs. What change in the B.P. readings is likely to occur in an otherwise fit man who is a heavy smoker and moderate drinker with a B.P. of, say, 165/110 if he completely abstains from these consolations for some months?

**A.**—There is no evidence that tobacco or alcohol plays any part in the production or maintenance of essential hypertension, and the patient under discussion is unlikely to show any improvement in his blood pressure if he abstains from them. It is true that transient rises in blood pressure have been described following smoking, particularly in those unaccustomed to tobacco and in individuals with effort syndrome or hyper-reactive vascular systems. These effects are apparently mediated by peripheral vasoconstriction of nervous origin and are quite different from the humoral vasoconstriction of essential hypertension. There is no evidence that the blood pressure is higher in smokers than in non-smokers, or that smoking has any uniform effect on the blood pressure of hypertensives. As emotional factors are believed to be important in maintaining hypertension, it would seem undesirable to put the patient to the strain of giving up tobacco entirely. On the other hand, both scientific and clinical evidence indicate that tobacco is harmful in Buerger's disease, in endarteritis obliterans, and in angina pectoris. In alcoholism the tendency is to low rather than high pressure. The patient should be told that moderation in all things is the golden rule in the treatment of hypertension, and he should practise a temperance which implies neither complete abstinence nor excessive indulgence in tobacco and alcohol.

#### How to Interpret the W.R.

**Q.**—To what extent does a positive Wassermann reaction or similar test indicate the presence of syphilis? If the test is positive when repeated, is one justified in starting treatment? How should one interpret (a) a weak positive, (b) a doubtful Wassermann reaction? To what extent does a negative reaction exclude syphilis?

**A.**—A positive W.R. carried out by a reliable pathologist is confirmatory evidence of syphilis if a patient has clear-cut signs of the disease. In the absence of signs of syphilis no positive serum test, no matter by whom it is done, even if it is positive on a second specimen, in itself justifies institution of antisyphilitic treatment. Quite a number of pathological conditions—mostly tropical diseases and therefore not likely to be met with in this country—may be responsible for false positive reactions. But such conditions as glandular fever, scarlet fever, pneumonia, late tuberculosis, diabetes mellitus, enteric fever, and malignant tumour—to mention only a few—have been incriminated from time to time. Recent vaccination also has been shown to be a cause. In addition there are people, very few it is true, whose sera appear to be "labile" in that they give false positive reactions without apparent reason.

In most of the above conditions the W.R. remains positive only for a comparatively short time, and tests repeated over a period of three months will usually show a weakening of the reaction or return to negativity. As a general rule, therefore, one should not diagnose syphilis on serum reactions alone unless they remain positive for at least three months. Meantime, a complete clinical examination of the patient should be carried out, including radiography of the heart and great vessels and examination of the cerebrospinal fluid.

The term "weak positive" should never be used. A "doubtful" reaction is one which is neither positive nor negative, and, except in an established case of syphilis, should merely serve as an indication for further investigation, both clinical and serological. A nega-

tive reaction does not exclude syphilis. The serum of a syphilitic patient gives a negative reaction in the first few days after the appearance of the sore, and not infrequently in the late stages of syphilis and especially in tabes dorsalis, not to say in syphilis which has been insufficiently treated.

#### Menopausal Obesity

**Q.**—It is well known that women about the time of the menopause tend to increase in weight. One of my patients has put on several stone and is very anxious to have this reduced. I prescribed thyroid, which is fairly effective, but I am concerned as to the effect of continued doses over a long period. Is there any other line of treatment which is effective, in addition to dieting, which the patient is already carrying out?

**A.**—The increase of weight at the menopause is probably associated with hypertrophy of the pituitary and adrenal glands at this time, although a great deal depends on genetic constitutional factors. There is no known "anti-adiposity" hormone yet available. Thyroid is not a specific, and even taken in doses sufficient to cause toxic symptoms it is unlikely to be fundamentally helpful. Nevertheless, it is useful in some degree, and I have not seen harmful effects from taking thyroid over a long period, providing the dose does not produce tachycardia or a pulse rate increased above normal. Dieting is helpful, but not fundamental treatment, and even on low-calorie diets the results are far from satisfactory in severe cases. Since there may be an associated element of salt-water retention, some patients respond in some degree to the additional therapeutic measure of mercurial diuretics—e.g., neptal, mersalyl, or salyrgan, 1 c.cm. intramuscularly, twice weekly, preceded the day before by 1 g. of ammonium chloride in capsule, t.d.s. Exercise and massage are also of some slight value.

#### Early Suckling

**Q.**—I have found recently in domestic midwifery practice that many midwives and nurses are advising mothers not to put the baby to the breast until the third day, the idea apparently being to prevent too much congestion of the breasts with milk and the resultant pain and discomfort to the mother. This is contrary to my teaching, which stressed the value of colostrum, etc. Is there anything in this new idea?

**A.**—There is no evidence that suckling during the first few days of the puerperium causes abnormal congestion of the mother's breasts, or that the postponement of suckling until the third day reduces any discomfort the mother may have when the milk comes into the breasts. The mother must get to know her baby and the baby must learn to suck, and what better time than the few days before the milk begins to flow? And suckling is the best stimulant to a good supply of milk. Colostrum is also said to contain protective substances and to have a beneficial laxative action. The practice of advising mothers not to put the baby to the breast until the third day should therefore be discouraged.

#### Hypnotics and Sulphonamides

**Q.**—Which is the most suitable (a) hypnotic, (b) analgesic during treatment with the sulphonamides? (c) Is acetyl salicylic acid safe during such treatment?

**A.**—The only hypnotic or analgesic drug particularly contra-indicated during sulphonamide treatment is amidopyrine. This, like the sulphonamides, occasionally causes agranulocytosis, and the combination of the two acts synergically and is very much more liable to do so. It should not be forgotten that amidopyrine (also known as pyramidon) is included in various sedative preparations known by proprietary names: these include both ethical products and patent medicines. Among the former are allonal, amidophen, cibalgin, compral, gardan, sinepan, trigemin, and vcramon.

#### Fasciculating Muscles

**Q.**—A man in the early thirties has for several years complained of involuntary contractions of muscle fibres. The contractions are identical with those fibrillating twitchings that most people have sometimes felt in the eyelids. In this case, however, they are on a larger scale and may affect any muscle in the body, but chiefly thighs, upper arms, eyelids, and quite a large number of fibres may be involved. The previous health has been good. There is no wasting but some tendency to obesity. No loss of muscular power. C.N.S. appears normal, but knee-jerks are unobtainable at times, and when present are very slight.

**A.**—This is an excellent description of a rare condition in which the muscles fasciculate without any evidence of any motor neurone disease. Although it is rare the condition is well recognized by neurologists, to whom it is usually referred as amyotrophic lateral sclerosis. The prognosis is good and no disability results, although, occasionally the subject will complain of a little fatigability. The only treatment required is explanation and reassurance.

## Ejaculatio Praecox

**Q.**—A patient aged 35 complains that for the past 2½ years he has suffered from precipitate orgasm. The orgasm itself is normal, with normal seminal emission, but always occurs as the penis is being introduced into the vagina. He is not sterile, and a child has been conceived under these circumstances. During the previous five years of married life coitus was quite normal. It is preying on his mind, he more so because his wife is showing signs of emotional stress.

**A.**—It is impossible to give an adequate reply to this question without a full psychiatric history of the case. Ejaculatio praecox is a symptom of a great variety of psychoneurotic disorders from mild hysteria to latent homosexuality. Some light on the aetiology of the condition is thrown by descriptions of apparently analogous cases in married men of the same age in Dicks's *Clinical Studies in Psychopathology* (Edward Arnold, 1939). In general it has often been observed that the age between 35 and 40 is a critical one for men, characterized by disturbances of a psychosexual order. This crisis seems to be part of a process of maturing, but may bring to light previously unsuspected conflicts. Where this occurs there is only one course—namely, a consultation with a psychiatrist, preferably for both marriage partners. No rule-of-thumb remedy is at hand. In view of the previously normal function the prognosis with adequate psychotherapy is probably hopeful in this case.

## Disseminated Sclerosis

**Q.**—Is there any effective treatment for disseminated sclerosis? I have a patient who contracted the disease about six years ago with the usual retrobulbar neuritis. She has now much pain and weakness in the arms.

**A.**—There is still no specific treatment for disseminated sclerosis. The claims which have been made for different therapeutic agents have mostly been due to the association of a spontaneous remission, which is characteristic of the disease. None of these agents, which include arsenic, serum, and vaccines, have been proved beneficial in controlled trials. There is, however, much to be done with the treatment of symptoms. This includes physiotherapy, relief of bladder symptoms, re-education in defective functions, and, most important, the maintenance of hope.

## LETTERS, NOTES, ETC.

## A "Gastric Board"

Capt. C. N. JEFFRIES (Army Dental Corps) writes: The object of the "gastric board," mentioned by Brigadier Edwards and Lieut.-Col. Copeman (Nov. 20, 1943, p. 640), is research into the causation of dyspeptic disorders, but to a dental surgeon the board appears to suffer from a grave omission. Consider the physiology of normal digestion: (1) a lump of food is cut off by the incisor teeth; (2) it is torn to shreds by the molar and premolar teeth, and mixed with saliva with the aid of the tongue and cheek muscles; (3) the prepared bolus is swallowed; (4) the fundus stores the bolus and surrounds it with gastric juice; (5) the pyloric antrum finishes the grinding process and mixes the food with the gastric juice. Failure of stage 2 will upset stage 5, because the food will require an excessive time to be broken down, and its surface area is too small to allow the gastric juice to act throughout the whole mass. The result is, therefore, hyperchlorhydria, not due to hypersecretion but to insufficient digestion. This process may in time lead to hypo-secretion, but in any case a disturbance of function will result. Stage 2 may fail either because of the habit of not chewing each mouthful or because of loss of teeth or the wearing of inefficient dentures. Out of 217 "non-ulcer" cases no fewer than 180 were classed as "no physical disease detected (functional dyspepsia)" and only 37 had progressed to the presence of physical lesions which could be diagnosed. It would be useful to know how many of these patients had deficiencies of their masticatory apparatus. The inclusion of a dental officer in the "gastric board" may lead to some useful conclusions on the aetiology of the conditions under examination. This is a field where dentistry can be called upon to play its part, and the dental surgeon can here contribute his share to preventive medicine.

## First Aid according to St. John's

Dr. BEAUMONT COMERFORD (Tolleshunt Darcy, Essex) writes: I have long wondered when a new textbook on first aid would be published. The subject-matter must often be quite unintelligible to the untutored recipients, and the lecturer himself may be a little at sea in his knowledge of these surgical catastrophes and their treatment in first aid. His cross-examining listeners may cause him to camouflage some of his answers. Dr. Truman in his letter (p. 703) stressed that the possession of this book "is a Tommy-gun to a child." The first-aiders may, if heroic, do some harm to the public. When a house officer at a London

hospital I saw a dead man brought in by the police: a handkerchief which had been twisted by a baton was still *in situ* on the thigh. The haemorrhage had come from a varicose ulcer of the leg. I was sorry for the constable; he was only doing what he had been told, and this tragedy had happened. At the inquest I remember stressing that the man had died of haemorrhage, but was not asked why.

## Localized Postural Oedema

Dr. E. L. GAVIN (Kilbeggan) writes: I was much interested in the reply given in the "Any Questions?" column to the query on localized postural oedema (May 13, p. 697). Has any work been done on the B.S.R. in this condition? At present I have two cases very similar to those described, but in each case the B.S.R. is very high (over 40 mm. in 1 hour, micro method). In view of this, and of a previous history of vague rheumatic pains, I am treating them as cases of latent rheumatic "fever" despite any clinical evidence of this.

## Two Answers

Dr. LEONARD LEY (Great Yarmouth) writes: I was interested in two of your questions in the issue of May 27. As regards coitus during pregnancy (p. 737), I am firmly convinced that this is the most frequent cause of miscarriage, and in the course of my career I have enabled numerous women to have full-term pregnancies after repeated abortion by forbidding intercourse.

The other was "a patient's dilemma" (p. 738), which amused me by the fact that it was such an excellent example of the profession's subservience to science in place of common sense. The victim suffers from nervous diarrhoea in church and is to be married, and feels sure he cannot "hold out" in church. Your correspondent deals at great length with the question but omits the obvious advice of a registry office.

## Implantation Cancer

Dr. HAROLD J. SELBY (Newnham, Glos.) writes: Under the heading "Any Questions?" (May 6, p. 665) you are asked if any case has ever been recorded of cancer of the penis following intercourse with a woman suffering from carcinoma of the cervix. In view of the answer given to this question the following may be of interest. Both cases occurred in my practice. Mr. A. consulted me in March, 1933, at the age of 50, on account of a "sore" on the glans penis. He had first noticed this two weeks previously. Section proved it to be an epithelioma. He was treated with radon seeds. Two months later severe haemorrhages occurred which the patient only just survived. By October healing was almost complete and by the end of the year all was well. No recurrence has taken place and the patient is alive and well. In October, 1937, his wife consulted me at the age of 55 on account of vaginal haemorrhage. Examination revealed an extensive new growth. Section proved this to be a columnar-celled carcinoma. She was treated with radium, but only survived till September, 1938. Admittedly there is a gap of four, nearly five, years between the cure of the one and the discovery of the other; but the cervical carcinoma was extensive and inoperable when discovered, so that this gap was certainly much less than 4½ years and possibly very much shorter.

## An Old Midwives' Tale

Dr. NORMAN GOORNEY (London, S.E.10) writes: The viability of a seven-months babe and the non-viability of an eight-months have recently been discussed by your correspondents, who have whittled the origin of this down to the sixteenth century. I assure them that its origin goes back much further. It is written in the Jewish Talmud, Tractate Revomuth, page 80, and is therefore accepted as true by all learned Jews since 2,000 years and more ago when the Talmud was scribed. It is to be found for the first time in medical literature in the writings of the famous Jewish physician of the twelfth century known as Rashi.

## Unusual "Deficiency" Diseases in Barbados

Dr. J. F. C. HASLAM (Director of Medical Services, Lusaka, Northern Rhodesia) writes: Dr. M. Lattey of St. George's, Bermuda, has stated in your issue of Feb. 12, p. 244, that while working in Barbados he found two conditions which he had not seen described anywhere, and he asks whether anyone else has seen those conditions. Dr. Lattey has called the first condition to which he refers "deficiency nephritis." I cannot say that I remember having seen that condition in Barbados when I lived and worked there, but I now feel fairly confident that some at least of the large amount of nephritis which occurred, and perhaps still occurs, in British Guiana may be connected with a dietetic deficiency. Many have speculated on the possible causes of the nephritis which has for long been a notable feature of the statistics of morbidity and mortality in British Guiana, and Dr. Lattey may find it worth his while to write to Dr. Wase Bailey, who is now chief medical officer of Barbados, who wrote, about 1925, a very interesting study of nephritis in British Guiana.

## CONTROL OF SCABIES BY USE OF SOAP IMPREGNATED WITH TETRA-ETHYLTHIURAM MONOSULPHIDE ("TETMOSOL")

BY

R. M. GORDON, M.D., Sc.D., F.R.C.P. T. H. DAVEY, M.D. K. UNSWORTH, B.V.Sc., M.R.C.V.S.\*

F. F. HELLIER, M.D., F.R.C.P. S. C. PARRY, M.R.C.S., L.R.C.P., D.P.H.

Lieut.-Col., R.A.M.C.

AND

Capt., R.A.M.C.

J. R. B. ALEXANDER, M.B., B.Ch.

Capt., R.A.M.C.

It is now generally recognized that scabies spreads from one individual to another by the transference of the mite causing the disease, and that this transference may be direct or indirect. Indirect transference is responsible for a minor proportion of infections, and may be efficiently controlled, when necessary, by disinfection of fomites. In direct transference, which is responsible for the majority of infections, the more intimate the contact the greater the chances of spread: hence scabies is often spoken of as a venereal disease, though it would be more apt to call it a family disease, in which the highest proportion of infections are acquired between husband and wife, parent and child, and so on. Up to the present time the only method used to control the direct spread is by treatment of the infected individual, and, with the exception of Johnson's (1943) suggestion that persons likely to be in contact with cases of scabies should dip their hands in solutions of benzyl benzoate, we are not aware of any proposed method of prophylaxis which might be used by the individual to protect him against the disease.

The idea of controlling scabies by the use of soap impregnated with tetmosol originated in animal experiments with *Notodres*, the results of which have already been published (Davey, Gordon, and Unsworth, 1944). Since the publication of that paper we have extended our observations to include human cases caused by *Sarcoptes scabiei*, and we here present the results of these investigations, together with some of our original observations.

In view of the high sarcopticidal activity of tetmosol in human and animal scabies (Gordon and Seaton, 1941; Percival, 1942; Jennings, 1942; Clayton, 1943) it appeared to us that, if the drug could be incorporated in soap and still retain its potency and non-irritative properties, it would then be available for prophylaxis and possibly for the treatment of mild infections without the necessity for medical supervision. In the Army, for instance, or in dealing with crowds of refugees, tetmosol-impregnated soap could be issued without the need for parades and disciplinary measures. Similarly, in an outbreak of scabies in factories, asylums, schools, and similar concentrations of people, it might be possible to control the infection by the provision of impregnated soap at the wash-basins. Johnson (1943) has written: "It may be said . . . that if all the mites on the hands and wrists of all patients alone could be killed (e.g., by dipping in benzyl benzoate solution), then about 60% of all the parasites would be eliminated. This might have a progressive and great effect on the reduction of the disease." We doubt whether Johnson's suggested treat-

ment would be carried out in the absence of supervision, but we believe that a tablet of tetmosol-impregnated soap of normal appearance would arouse no antipathy and would be used.

In order to ascertain whether such a soap could be employed to control scabies it was necessary to establish that tetmosol could be successfully combined with soap and remain stable on storage. This was accomplished by Imperial Chemical Industries, Ltd., in collaboration with Messrs. Unilever, Ltd., and the soap was found to remain chemically unaltered when tested at monthly intervals over a period of a year. There still remained the question whether the use of such a soap would result in dermatitis, and whether tetmosol would retain its sarcopticidal properties when used in this form.

### Risk of Dermatitis from Tetmosol Soap

The risk of dermatitis from any drug will obviously be affected by the concentration of the drug, the idiosyncrasy of the individual, the period of time over which it is used, and the frequency of its application.

It is difficult to give a reliable average figure for the number of times the ordinary person washes during the course of the day, for the length of time he spends on the process, or for the degree of dilution of the soap applied to the skin. By studying the ablutions of a number of individuals, however, we found that they spend about 40 seconds in lathering either the face or the hands (in the case of a bath the whole body is lathered for about 60 seconds), and that if a drug is incorporated to the extent of 10% in soap its dilution when applied to the skin is in the region of 1.8%; further, we found that it is the common practice to wash off the soap with about six changes of water. On these observations our subsequent trials with the soap were based. The frequency of washing obviously varies according to the individual, but a rough idea of the extent to which soap is used in the Army was obtained by sending a questionnaire to 150 R.A.M.C. officers, whose replies suggested that almost 100% of the men wash the hands and face at least once a day and the body at least once a week, and that the majority probably do not use soap on the hands and face more than two or three times a day.

Evidence from the literature suggests that tetmosol, when applied to persons with dermal lesions due to scabies, only occasionally produces dermatitis (Percival, 1942; Clayton, 1943). Our own experiments with tetmosol soap confirm these findings: 242 patients suffering from proved scabies received three baths with 20% tetmosol soap during the course of six days; of these, four developed dermatitis; in three of these cases of dermatitis patch-tests showed that the reactions were not due to tetmosol; the remaining case was not tested. It follows, therefore, that only a low incidence of dermatitis is liable to occur after the use of tetmosol soap when applied for short periods to the skin, even when this has already been damaged by scabies. These results, however, did not directly

\* Working under a grant from Imperial Chemical (Pharmaceuticals) Ltd.

concern us in the present investigation, since the point to be established was whether or not tetmosol soap, when applied prophylactically for long periods to the normal skin, was apt to produce dermatitis. This must remain unanswered for the time being, since it can only be determined by a prolonged use of the soap by a large number of people. We have, however, certain evidence which is of some value. In our own experiments three volunteers in the laboratory have used soap containing 5% tetmosol twice daily on the face and hands, and once a week on the body, for two months without dermatitis resulting. Subsequently, one of the volunteers similarly used 10% tetmosol-impregnated soap for a further period of a year, and another used 20% tetmosol soap for a further period of six months, without ill effect in either case.

A further test over a shorter period was carried out by Major Kenneth Mellanby, R.A.M.C., who distributed two tablets of 10% tetmosol soap to each of 29 volunteers (conscientious objectors). All used the soap as long as it lasted, but the time varied with the care of the user; thus six men made it last only 14 to 18 days, but the remainder made it serve for as long as 63 days. The average for all users was 34 days. The following is quoted from Major Mellanby's report on "Skin Reaction":

"Six subjects observed no unusual sensations when they used the soap, but 23 of the 29 volunteers reported that some irritation of the skin occurred. In 12 cases this was very slight and transitory—generally just a slight stinging of tender areas after soaking in a hot bath; had these subjects not known that they were using a special soap they might not have noticed this symptom.

"Nine volunteers complained of more serious irritation, but this caused no erythema or other skin reaction. These volunteers continued to use the soap until it was finished, and mostly found that, if anything, the irritation was less severe towards the end of the exposure. There is nothing to suggest that there would have been any danger in these subjects continuing to use the soap for long periods; they agreed to continue for longer if necessary.

"Two subjects reacted more severely, and in the first instance they used the soap for only two and five days respectively. Brigadier R. M. B. MacKenna has examined both these patients, and reports that they are both individuals with unusually sensitive skins. One is genuinely sensitive (but only slightly) to tetmosol; in the other the impregnated soap acted apparently as a primary irritant. In both cases the skin recovered completely when the use of the soap was discontinued. It is obvious that these two volunteers would be unable to use tetmosol soap permanently; but, if the soap were issued to a large population, individuals of this type would discover that the soap disagreed with them before any damage had been done. It seems likely that the proportion of such individuals in Southern Europe and the Balkans (where the soap might be most useful) is considerably lower than in this country.

"The general conclusion seems to be that most people will not be harmed at all by the soap. A small minority will find it a skin irritant, but this fact will be easily detected before any harm is done. There is no evidence to suggest that anyone is highly sensitive to tetmosol soap."

#### Sarcoptidicidal Properties of Tetmosol Soap when Used Therapeutically

##### In Animal Infections due to *Notoedres*

As already stated, observations on the washing habits of a number of individuals enabled an estimate to be made of the final dilution of the drug incorporated in soap when it reached the skin, and of the length of time during which the drug would be in contact with the skin. Infected rats were subjected to treatment similar to that which would be used by a person performing his ordinary ablutions. The infected area was washed for 40 seconds with a known dilution of soap lather. The soap was immediately washed off with six consecutive applications of clean swabs of cotton-wool dipped in clean warm water. Using this technique with soap containing 5% tetmosol (final dilution of the drug 0.9%) twice daily for periods of two to seven days, it was found that in only a few instances was the treatment followed by cure (8 animals treated, 1 cured)—that is to say, by the complete destruction of all mites in the treated area; such treatment, however, invariably resulted in the destruction of a large number of mites. By increasing the concentration of tetmosol in the soap to 20% a greater proportion of mites were destroyed, although, as before, the majority of cases were not cured (6 animals treated, 1 cured). Further experiments were now carried out in which the rats

were treated in a manner corresponding to a person taking a weekly bath—i.e., the washing period was increased from 40 to 60 seconds, and instead of the operation being repeated twice daily it was performed once a week. Six rats were treated in this manner: in no instance did a complete cure result, and, although there was a considerable reduction in the mite population as compared with controls, this was not so marked as in the case of 20% or 5% tetmosol when used twice daily.

##### In Human Infections due to *Sarcoptes scabiei*

Having shown that tetmosol soap possessed curative properties in respect of animal infections due to *Notoedres*, it remained to be shown whether it also possessed similar therapeutic effects in the case of human infections with *Sarcoptes scabiei*. Facilities for the investigation were obtained by arrangement with the War Office, soldiers suffering from scabies being sent to centres under our control. The total number of cases which received a full course of treatment was some 250, but owing to military exigencies only 110 were available for the entire subsequent observation period. In order to put the investigation on a scientific basis the following rules were rigidly adhered to and applied to all the cases recorded in this paper:

1. Every case recorded as positive was diagnosed by the finding of the live acarus.

2. All relapses were similarly diagnosed by the finding of the live acarus, any doubtful case being kept under observation until either a cure or a relapse had been definitely proved.

3. The bathing was supervised by a medical orderly, and the procedure was as follows: (i) The patient took a hot bath, using tablet of 20% tetmosol soap. (ii) The patient stepped out of the bath and, assisted by an orderly, was thoroughly lathered all over (except for the face and neck), attention being given to such parts as the feet, which might otherwise have escaped the application of soap. (iii) The patient stepped into the bath, rinsing off the soap. (iv) Thorough lathering with tetmosol soap was then repeated on the bath. (v) The soap was again rinsed off in the bath. (vi) The patient dried himself and dressed. (vii) Daily inspection were made, and any evidence of itching or skin reaction was recorded. In the case of treatment by six baths, these were given on successive days; in the case of treatment by three baths, some of the patients received their baths on the first, third, and fifth days; others on the first, third, and sixth days.

4. After treatment was completed, every case was kept under observation for a period of at least six weeks. So far as was possible, patients were recalled for observation at weekly intervals and where such frequent attendance was not possible each case was examined by one of us at least twice during the six weeks, one of these examinations always occurring at the end of the observation period.

**Results Obtained (a) After Six Baths.**—The first six cases in which the acarus was found were given one tetmosol-soap bath on each of six consecutive days. All were observed for six weeks after the completion of treatment. All six cases were cured.

**Results Obtained (b) After Three Baths.**—A total of 11 cases were treated by means of three baths with 20% tetmosol soap and were subsequently observed at intervals over a period of six weeks. Of these 110 cases, 88 (80%) were cured. In practically every patient, including some of those who were not cured, treatment was attended by an immediate disappearance of irritation, the man often getting his first sound sleep for several nights.

Of the 110 cases treated by means of three baths with 20% tetmosol soap 22 (20%) relapsed. In the majority of relapses the irritation persisted after treatment, but in a small proportion it disappeared completely for periods varying up to three weeks, the renewal of the irritation being often associated with the finding of the acarus.

It must in fairness be stated that these figures, for reasons beyond our control, are biased in favour of relapse. In the first place, it is probable that a number of the cases recorded as failures were really reinfections, as there was ample opportunity for re-exposure, particularly in the case of men returning to infected families. In only four instances, however, was it possible to obtain clear evidence of re-exposure to infection; these four cases have been omitted. Secondly, cases which relapse are noted earlier than those which are cured, as the latter are recorded only at the end of six weeks and so are more likely to be lost to view than those which have relapsed.

From the results recorded above it was clear that a high proportion of established cases of human scabies with well-marked lesions were cured when thoroughly washed on three occasions with 20% tetmosol soap, and that tetmosol soap was much more effective in curing natural infections with *Sarcoptes* in man than with *Notoedres* in rats.

The main object of our investigation, however, was to show whether tetmosol soap could be used as a prophylactic against the acquirement of the disease. The practical difficulties involved in a controlled experiment with human volunteers were found to be so considerable that this was not attempted. It was thought that, if it could be shown that the use of tetmosol soap protected rats against the acquirement of the disease when exposed to massive infection from their companions, this result, when considered in conjunction with the proved therapeutic value of the soap in human infections, would warrant its trial on a large scale in an infected human community.

#### Sarcoptidical Properties of Tetmosol Soap when Used Prophylactically

In order to test the prophylactic value of tetmosol incorporated in soap, white rats were confined in a large tank. Some of these received no treatment; others were washed over the entire surface of the tail with unmedicated soap, the soap, as before, being washed off with six fresh swabs dipped in warm clean water. The remaining rats were similarly treated, but tetmosol in various strengths was incorporated in the soap. After three days of treatment a number of rats suffering from severe *Notoedres* infection were introduced into the tank containing the uninfected rats, the tail-washing of the uninfected rats being continued. From now on, the rats were examined daily for gross evidence of infection, but the burrows were not opened up until the end of the experiment, when the animal was killed, the tail removed, and a careful microscopical examination made of all papules.

Although it appeared to us unlikely that impregnated soap applied for a short period at relatively long intervals would prove effective as a prophylactic, our first experiments were designed to imitate a person taking a weekly bath with tetmosol soap, the soap not being used during the intervening period. A series of five experiments were carried out using the technique described above. The results are shown in Table I.

TABLE I.—Showing, in a colony of 20 clean rats in constant contact with 6 rats heavily infected with *Notoedres*, the prophylactic effect of washing an area of skin (the tail) for 40 seconds once a week during three to five weeks with 5%, 10%, and 20% tetmosol soap

No. of Rats	Treatment	Period of Exposure to Infection in Days	Post-mortem Examination of the Treated Area (the Tail)	
			Average No. of Live Mites	Average No. of Eggs
7	Unmedicated soap	18 (1)	57	313
		22 (1)	115	640
		23 (3)	195	980
		25 (1)	131	747
		30 (1)	190	648
3	5% tetmosol soap	19 (1)	3	23
		22 (2)	14	69
7	10% tetmosol soap	24 (2)	24	82
		25 (3)	47	160
		30 (1)	17	67
		31 (1)	91	185
3	20% tetmosol soap	18 (1)	2	6
		22 (2)	0	0

It can be seen from Table I that neither 5 nor 10% tetmosol-impregnated soap, when used at weekly intervals, protected any of the rats from the disease. On the other hand, if the results following the use of the tetmosol-impregnated soaps are compared with those following the use of unmedicated soap it will be seen that in every instance the development of the disease had been controlled, so that fewer live mites and eggs were found in animals treated with impregnated soap than in those treated with ordinary soap. The table also shows that there is a tendency (which can be seen in almost all the series recorded) for the infection to become rapidly and progressively heavier with each day of exposure. This fact properly explains the apparent anomaly that a larger number of eggs and

live mites were found in rats treated with 10% tetmosol soap than in those treated with 5%, for the former series were exposed to massive infections for longer periods than the latter.

The results obtained by using 20% tetmosol soap were surprisingly good, considering the shortness of the application and the long interval between treatments: no mites or ova were found in the tails of the two rats which had four treatments in 22 days' exposure to infection; and in the remaining rat, which had 18 days' exposure to infection and three treatments, two mites and six ova only were found.

These experiments show that weekly treatment by washing with tetmosol soap of strengths varying from 5 to 20% did reduce the infection, in spite of the massive risk to which the rats were exposed. It is possible that weekly bathing with tetmosol soap might have greater value in the case of human beings than in the case of rats, for the risk of scabies infection in man is immensely less than among the rats recorded in these experiments. Even in a heavily infected person the number of mites present is relatively small in comparison with the enormous number found in such heavily infected rats as the carriers used in our experiments, and the same continuous and intimate contact does not exist between uninfected and infected human cases as it does in the rats in the above experiments. Moreover, it must be remembered that clean rats themselves rapidly became carriers, since untreated areas, such as the paws, nose, and ears, were soon heavily infected.

Having shown that a weekly bath with tetmosol soap protected only a small proportion of the rats exposed to infection with scabies, and reduced the intensity of the infection in the remainder, our next experiments were designed to ascertain whether daily washings with tetmosol soap would have a more marked prophylactic effect. They were planned in imitation of a person using 5% tetmosol soap for his daily ablutions, the technique used being the same as in the previous experiments. The results obtained are shown in Table II.

TABLE II.—Showing, in a colony of 18 clean rats in constant contact with 6 rats heavily infected with *Notoedres*, the prophylactic effect of washing an area of skin (the tail) for 40 seconds twice daily with 5% tetmosol soap

No. of Rats	Treatment	Period of Exposure to Infection in Days	Post-mortem Examination of the Treated Area (the Tail)
6	None	28 (1)	Live mites and ova — — —
		33 (2)	
		34 (2)	
		35 (1)	
6	Unmedicated soap	13 (1)	Live mites and ova — — —
		28 (1)	
		29 (1)	
		30 (2)	
		36 (1)	
6	5% tetmosol soap	25 (1)	No live mites, ova, or mite remains
		28 (1)	
		29 (1)	
		30 (2)	
		36 (1)	

The results recorded in Table II show that washing the skin twice daily with unmedicated soap has no protective value against rat scabies, but that similar washing in which 5% tetmosol is incorporated gives complete protection among rats constantly exposed to heavy infection for a period of 25 to 36 days. It will be noted that no mite remains were found in the treated area. In spite of this, papules were present, which were presumably caused by invading mites. If this presumption is correct the action of tetmosol would appear to be not that of a repellent but rather that of a lethal agent which destroys the mites after they have penetrated the treated area of skin.

#### Conclusions and Summary

Tetraethylthiuram monosulphide (tetmosol) when combined with soap in 5, 10, and 20% dilutions has been shown to retain its sarcoptidical properties.

In cases of rat scabies due to *Notoedres*, tetmosol soap was shown to produce a local therapeutic effect when used daily or weekly, the local infection being cured in some cases, the mite population being reduced in others.

In cases of human scabies six men suffering from *Sarcoptes scabiei* infection received five to six baths with 20% tetmosol soap on successive days; all were cured. A further series of 110 men received three baths with 20% tetmosol soap over a period of a week. All these cases remained under observation for at least six weeks, at the end of which period 88 (80%) were found to have been cured, and 22 (20%) to have relapsed.

Although it has been shown that the repeated use of tetmosol soap cures a high proportion (80%) of established cases of scabies, the soap is unlikely to supersede any of the standard methods employed which result in more than 90% cures. On the other hand, the simplicity of procedure involved in supplying the patient with a tablet of soap and instructing him to use it when bathing suggests the possible value of the soap if it is used therapeutically in communities which have become disorganized as a result of war, and in which it is not practicable to employ standard methods of treatment.

In the case of clean rats heavily exposed to *Notoedres* infection from their companions, washing the tail once weekly with 5 and 10% tetmosol soap was followed by a marked reduction in the number of mites developing in the skin as compared with controls washed with unmedicated soap. When 20% tetmosol soap was similarly used once weekly the effect was more striking, two rats being completely protected against infection over 22 days, and the remaining rat developing only a very light infection.

In contrast to the partial protection provided by weekly washing with tetmosol soap, the regular use of 5% tetmosol soap twice daily on the tails of clean rats constantly in contact with companions suffering from severe *Notoedres* infection gave complete protection to the treated area during periods of 25 to 36 days (the duration of the experiment). Little or no protective action followed the use of unmedicated soap.

It is considered that the results recorded justify the belief that the generalized use of tetmosol soap in an infected community would reduce the incidence of scabies by sterilizing some existing cases and by destroying the infection in freshly invaded persons. Such generalized use, however, will only be possible if it is found that a high incidence of dermatitis does not follow prolonged use of the soap. We have shown that the incidence of dermatitis following the use of the soap for short periods is low, and that it was low also among a small number of people tested over a prolonged period; but no estimate can be made of the risk of dermatitis until an extensive trial with a large number of individuals has been carried out.

## THE CARRIER STATE IN SONNE DYSENTERY

BY

J. GORDON HAILWOOD, M.D., D.P.H.

Major, R.A.M.C.; Hygiene Specialist

Since the discovery of *B. dysenteriae* Sonne in 1915 accounts have been published of many epidemic outbreaks of Sonne dysentery, but rarely has the original carrier in any single outbreak been traced. In fact, Bloch (1938) states: "It is generally accepted that symptomless chronic carriers of bacillary dysentery are rare"; while Buckle (1938), in the course of an investigation of an outbreak of Sonne dysentery in a mental hospital, says: "Tracing the cause appeared a hopeless task. . . . Proved persistent carriers of this organism are apparently rare, and . . . little investigation has been done to elucidate this point."

The appearance of Sonne dysentery in the Army in many places throughout the country, and particularly the large outbreak in a regiment which I propose to describe in some detail, have led me to search the literature for recorded outbreaks of this disease, especially noting whether or not an original carrier was found in each outbreak. The following table covers most of the recorded outbreaks in this country. It is seen that in only one outbreak—that reported by Thornton and Darmady (1938)—was an original carrier found.

In view of these facts and the suggestions that chronic carriers of Sonne dysentery are rare, the severe outbreak which occurred in an Artillery regiment in July-Aug., 1943, is of

special interest, since a chronic symptomless carrier who worked in the cook-house was traced as the originator.

Author	Place	No. of Cases	No. of Cases Bacteriologically Positive	Cause	Remarks
Weisman (1927)	Glasgow	—	80	Milk	No carrier found
Laws (1936)	Mental hospital	113	75	No cause found	Suggested that mild or symptomless cases were missed and they spread the infection
Parry and Peters (1936)	Mental hospital, Bristol	32	9	" "	Case-to-case spread
Bloch (1938)	Institution, Glasgow	—	78	No evidence of spread by food, milk, or water	Origin not traced
Buckle (1938)	Mental hospital	115	74	No cause found	Six positives among staff, nurses, and porters, but not cooks
Savage (1938)	Somerset	130	?	Ice-cream	No carrier or specific source of infection ascertained
Thornton and Darmady (1938)	Mental colony	—	30	Two symptomless carriers—one a dish-washer	
Cruickshank and Swyer (1940)	—	32	29	No carrier found	Suggested case-to-case spread
Graham (1942)	School	52	Only 5 tested, who were positive	No carrier or infecting agent found	All kitchen staff examined, but negative
Irvine (1942)	Leicester village	73	17	No carrier found	Suggested case-to-case spread
Green and Macleod (1943)	Somerset town	About 400	?	Water	No carrier found. Eight water-works employees examined: all negative

## The Outbreak

An Artillery regiment, consisting of three batteries and with a total strength of about 900 men, was at a practice camp in Wales when an outbreak of diarrhoea occurred. This started about July 20, 1943, and appears to have been at its height about Aug. 1, but no examination of faeces was done until Aug. 3. However, from this date every soldier with a history of diarrhoea since the start of the outbreak had specimens of faeces examined. Those with a positive result were admitted to isolation hospital immediately, while negatives had further examinations of faeces until three specimens had been found negative. Altogether there were 292 cases of diarrhoea (32.5% of the total strength), of which 81 were positive for *B. dysenteriae* Sonne. It is probable that the infection had died out in many of the remaining 200-odd cases before the stools were examined, as the attack of diarrhoea in some cases had been two to three weeks previously. Treatment in isolation hospital with sulphaguanidine resulted in the rapid cure of all cases, including the carrier.

This outbreak occurred in what was virtually a closed community, since the camp was isolated and outside amenities were few. The water supply was satisfactory, and was regularly examined bacteriologically. The general lay-out of the camp and the sanitary arrangements were also satisfactory. There was no fly nuisance; food-storage facilities were good; and both larders and cook-houses were clean and well kept. Food for the whole camp was drawn from a single central store. There were four main cook-houses in the camp, one of which served the permanent staff of the camp, while the other three were staffed by and served the visiting regiment.

No cases arose among the permanent staff, and no evidence of diarrhoea was found among the cooks of the staff cook-house. Cases, however, occurred among men served from all the cook-houses used by the visiting regiment. All the cooks and orderlies in each cook-house were paraded and questioned carefully whether they had had diarrhoea during the last 12 months. Twelve gave a history of diarrhoea within the period of the outbreak, and, in addition, one in June, one in May, one in Feb., 1943, and one in Aug., 1942. These men were all excluded from the cook-house immediately and their stools

examined on six occasions before being considered negative and allowed to return to duty. Six positives were obtained among these men. All other cook-house personnel who denied a history of diarrhoea had three specimens of faeces examined, but were allowed to continue their work in the cook-house without interruption.

The exclusion of suspicious cooks from the cook-house was completed on Aug. 11; the last fresh case of enteritis occurred on Aug. 13, and I considered that by Aug. 20 the regiment could be considered free from infection. Owing, however, to the expected activities of this regiment, Higher Authority considered that the risk of another outbreak should be excluded with certainty, and eventually every man in the regiment who had not previously been examined, because he gave no history of diarrhoea, had two specimens of faeces tested. It is of interest that not a single further positive result was obtained.

### The Carrier

At least one Sonne-positive case was found among the personnel in each cook-house, but only one man whose history of diarrhoea was outside the limits of the incubation period. This was Gunner P., who gave the following history.

While stationed in Scotland in Aug., 1942, he had been admitted to a camp reception station with acute enteritis, pyrexia, colic, and frequent stools containing blood and mucus. He was in bed for about 7 days, but no investigation was carried out. In Nov. 1942, he was posted to this regiment, and in Feb., 1943, was employed in the sergeants' quarters. His duties included providing the sergeants with cups of tea, bread-and-butter, etc., at various times. At this period there was a mild outbreak of enteritis in the regiment—some 80 cases in all, of which the majority were sergeants. No investigation was carried out, however, and the outbreak apparently died down. For some months he was then employed on the guns, but on July 7 he was detailed for duty as orderly in one of the regimental cook-houses at the practice camp. His job was mainly cutting bread-and-butter. The first cases occurred about July 20, and were among the battery personnel served from this particular cook-house.

It is certain that in the course of his duties Gunner P. visited the other regimental cook-houses to lend or borrow on numerous occasions, and thus infection would be conveyed to food and personnel in them, with consequent spread of the epidemic to the remaining two batteries. It was equally certain, for administrative and other reasons, that he did not so visit the permanent staff cook-house. It has been noted that no cases occurred among the personnel served from there. This man had had no symptoms since his moderately severe attack 12 months previously, but his stool showed a heavy infection of *B. dysenteriae* Sonne.

### Comments

It is evident that Gunner P. was the carrier in this outbreak, since he was the only Sonne-positive found who had not had any symptoms within the limits of the epidemic. He had had, in fact, no symptoms whatsoever since his enteritis of 12 months previously, while his history was exceedingly suggestive and his work as a cutter of bread-and-butter was ideal for the spread of the organisms. There can be no doubt that here was an outbreak of Sonne dysentery spread by food—by far the commonest vehicle—infected by a chronic symptomless carrier of a year's duration.

I consider that symptomless carriers are responsible for many of the recently frequent outbreaks of Sonne dysentery in this country. However, I would suggest that they are only symptomless in that they have had no symptoms for, maybe, many months, but that with careful questioning a history of diarrhoea, or perhaps just "looseness of the bowels," at some time in the past will be obtained. This opinion is borne out by the fact that in the outbreak described above not a single positive stool was obtained from the remaining two-thirds of the regiment who were subsequently examined but who had given no history of illness previously. In other words, no positive case was found that did not give a history of diarrhoea at some time.

It is impossible to over-emphasize the importance of careful questioning of all persons connected with food preparation in any outbreak of dysentery; this, followed by the segregation of all those with a history of diarrhoea, however slight, will almost always put an end to the outbreak. Gardener (1929), when discussing asylum dysentery, stated that carriers are the main source of infection; while Hobbs and Allison (1942) have also

recently stressed the importance of carriers and ambulant cases in the spread of the disease. However, although the carrier state is generally admitted, only rarely has a single definite carrier been found in an epidemic of any size. Yet it is essential to isolate such a carrier before one can be satisfied that any such epidemic has been finally brought to an end. Milk, water, food, have all been involved in some or other outbreak, but often the human factor is neglected. The vehicle—and cold uncooked foods should always be primarily suspect—is a link in the chain which will, if carefully followed, bring the investigator to the human focus of the infection.

### Summary

An outbreak of Sonne dysentery in a virtually closed community is described.

It was discovered that a chronic symptomless carrier had spread the infection by food during his duties in the cook-house.

The removal of all infected cooks from the cook-house immediately stopped the outbreak.

The opinion is put forward that the so-called symptomless carrier of Sonne dysentery is common, but that a history of diarrhoea at some time in the past can usually be obtained.

I wish to thank Capt. C. E. Perry and Lieut. Madison, R.A.M.C., for their help at the scene of the epidemic; Dr. R. M. Fry of the E.P.H. Laboratory Service for his reports on numerous specimens; and the D.D.M.S., Western Command, for his permission to publish this account.

## AN ANALYSIS OF COLLES'S FRACTURE

S. C. ROGERS, B.S., M.R.C.S.

Late Casualty House-surgeon, St. Mary's Hospital, Paddington

"No two Colles's fractures are alike."—SPEEO (1935).

At first when examining and reducing Colles's fractures this aphorism seemed too true. Later, recurring types were noted, and it was decided to review the radiographs of a series of fractures around the lower end of the radius seen at this hospital between Jan., 1942, and Oct., 1943.

Descriptions of the varieties of comminution of the lower radial fragment in Colles's fracture are absent from surgical textbooks and vague in works on orthopaedics. Comminuted forms are recognized by Platt (1932) and others, and a vertical posterior marginal crack involving the wrist-joint is described by Clayton and Edwards (1929).

Very divergent views on the cause of poor end-results are given. Platt (1935) and Taylor and Parsons (1938) stress the bad prognosis of coincident fractures of the base of the ulnar styloid and injuries to the triangular fibrocartilage, but do not think involvement of the ulnar notch of the radius important. Grasby and Trick (1929) find that imperfect reduction leads to osteo-arthritis of the inferior radio-ulnar joint. Clayton and Edwards (1929) and Bankart (1929) stress the reduction of backward rotation and Mayer (1939) of supination. Finally Lewis (1934) blames lack of co-operation by the patient in active exercises. Thus, given satisfactory reduction and its maintenance and the adequate supervision of active exercises, injuries to the base of the ulnar styloid and the triangular fibrocartilage appear to lead to most trouble. In this analysis Colles's fractures are divided into types with different degrees of damage and mechanisms. A short anatomical account of the radio-ulnar joint will enable the discussion to be followed more readily.

### Anatomy

The ulnar collateral ligament of the wrist is attached to the tip of the ulnar styloid process. The apex of the triangular

fibrocartilage of the inferior radio-ulnar joint is attached to the floor and walls of the small pit at the radial side of the base of the ulnar styloid. This fibrocartilage spreads out to a linear insertion along the edge of the ulnar notch of the radius, and its margins are prolonged into the loose anterior and posterior capsule of the radio-ulnar joint. Thus a fracture across the base of the ulnar styloid or the splitting off of the postero-medial corner of the lower end of the radius enables the main portion of the radius to displace the fibrocartilage without seriously injuring it.

### Analysis and Discussion

In all, 328 fractures around the lower end of the radius have been analysed; 13 epiphyseal injuries and the rare greenstick Colles's fracture have been included. The common greenstick fracture of the radius, fractures of the lower shaft of both forearm bones, and carpal fractures have been excluded.

The 219 Colles-type fractures fall into five groups with surprising clarity:

(A) 59 simple Colles's fractures—i.e., fractures not involving the radio-carpal articular surface, but often with fragments of the posterior cortex flaked off, usually including Lister's tubercle (see Fig. 1).

FIG. 1.—Simple Colles's fracture with severe displacement and shortening. Probable rupture of triangular fibrocartilage. Note tubercle of Lister in flake off posterior cortex. (Group A.)

(B) 108 fractures with an oblique postero-medial fragment containing part of the ulnar notch of the radius and so the attachment of the triangular fibrocartilage, and involving both radio-carpal and radio-ulnar joints (see Fig. 2).

FIG. 2.—Colles's fracture with small postero-medial fragment. Medial displacement and shortening of this fragment suggests posterior subluxation of intact fibrocartilage. (Group B.)

(C) 39 "comminuted Colles's fractures" in which a fracture of the base of the radial styloid passes from the centre of the radio-carpal articular surface obliquely to the lateral surface of the radius, in association with the above postero-medial fragment (see Fig. 3).

(D) 11 fractures with a vertical fracture of the radial styloid, with or without a postero-medial fragment.

(E) 2 fractures with a transverse fracture of the base of the radial styloid passing from the articular surface directly laterally, without a postero-medial fragment.

The other 19 cases include 8 fractures of the styloids (2 ulnar and 6 radial), 5 marginal fractures of the radius, and 6 Smith's fractures.

FIG. 3.—Comminuted Colles's fracture with oblique fracture of radial styloid and large postero-medial fragment. Note backward displacement of whole ulnar styloid and fibrocartilage. (Group C.)

A detailed analysis of the Colles's fractures according to the presence of shortening of the postero-medial corner of the radius, the type of fracture of the ulnar styloid, and the severity of the displacement of the main fragments, was made and on its results the following remarks are based.

Clayton and Edwards's (1929) observation that it is the long narrow type of ulnar styloid that breaks at its tip, whereas the short broad type is less often fractured, has been confirmed.

In general, basal fractures of the ulnar styloid are rare when displacement is minimal and frequent when severe, especially if shortening at the radio-ulnar joint is present. In fact, there are only 16 cases out of 219 in which the presence of shortening at the radio-ulnar joint without a basal fracture of the ulnar styloid suggests a rupture of the triangular fibrocartilage. A postero-medial fragment is present in all but one of these 16 cases, and in many the extreme medial displacement of this fragment suggests a posterior subluxation of the intact ligament rather than an actual rupture. This explains the rarity of instability of the radio-ulnar joint as a late sequela (Hyman and Martin, 1940), and the usual excellent return of pronation and supination.

Group B contains most of the more severe fractures and shows many basal fractures of the ulnar styloid. The postero-medial fragment varies in size from an apparent avulsion of the insertion of the radio-ulnar fibrocartilage to a fragment like the isolated posterior marginal fracture, and its vertical direction suggests that it is a compression fracture. In group C the bending force that produces the Colles's fracture is combined with a compression force directed backwards and laterally, splitting off the posterior and lateral portions of the articular surface and leaving an anterior marginal fragment which is sometimes rotated slightly forward (see Fig. 3). This compression and lateral displacement mechanism accounts for the frequency of shortening and of basal fractures of the ulnar styloid. Group D is small, and represents a compression fracture in which the force is directed almost vertically down the shaft of the radius. Group E combines the Colles with a transverse shearing fracture of the radial styloid—one of the chauffeurs' fractures.

All these types of secondary fracture may occur isolated, and similar comminutions may be seen in Smith's fractures.

### Reduction

A general method of reduction is described and discussed below. The strength of the manipulations should be varied with the exact displacement seen in antero-posterior and lateral radiographs.

Nitrous oxide anaesthesia is satisfactory provided a dry slab is prepared before reduction, that during plastering the slab is rendered almost dry, and that hot water is used. (This accelerates setting of the plaster.)

1. Strong steady traction on the hand in slight radial deviation obtains disimpaction, overcomes shortening at the radio-ulnar joint, and, if strong enough, secures anterior cortex-to-cortex apposition.
2. Strong traction in 30 degrees palmar flexion with direct pressure, by the chin if necessary, over the lower fragments corrects backward rotation without further trauma to the joint capsule.
3. Traction in ulnar deviation and pronation corrects radial deviation and supination.
4. Direct antero-posterior and lateral compression moulds the fragments.

This method is similar to many others, but I would stress that, unless disimpaction is carried out by strong traction in radial deviation, shortening at the radio-ulnar joint and posterior subluxation of the triangular fibrocartilage may persist.

The method of Sir Robert Jones (or, rather, of Hugh Owen Thomas—see Parker, 1929) is satisfactory if there is no shortening or gross comminution, but a generally applicable method is preferred.

#### Immobilization and After-treatment

Reduction is confirmed and its stability tested. The arm is held in moderate traction in the mid-pronated position with considerable ulnar deviation and no palmar flexion. The thumb is opposed, abducted, and flexed to meet the flexed index finger. A 4-circle plaster back slab is applied gripping the anterior surfaces of radius and ulna and the dorsal surface of the first metacarpal, and taking a long grip of the upper end of the ulna. This position helps to maintain the full length of the radius. The slab is secured with a dry cotton bandage. No moulding is performed if the fracture is stable, but if unstable—as, rarely, it is—careful moulding to the anterior radial concavity is essential.

Reduction is checked radiographically, and graduated and vigorous active exercises to fingers, elbow, and shoulder are started immediately under supervision. A high sling is worn for three or four days. The plaster is removed after five weeks and the exercises are intensified. The patient usually returns to light clerical work after one week (in plaster), to light manual work after seven weeks, and to heavy work after about nine weeks. He is discharged when his range of movement is approaching that of the normal side and he has been doing his usual work without complaint for at least a week.

It is hoped to discuss in detail the results of a smaller series later.

#### Summary

238 fractures about the lower end of the radius have been analysed and shown to fall into certain definite groups. Their mechanisms have been discussed and their treatment outlined.

I am much indebted to Mr. V. H. Ellis, honorary orthopaedic surgeon to St. Mary's Hospital, for his encouragement and helpful criticism; and to my fellow casualty house-surgeons for their co-operation and stimulation.

A message from Washington announces the appointment of Dr. Wilbur A. Sawyer, of New York, as Director of Health of the United Nations Relief and Rehabilitation Administration. He will be assigned to Washington and will be in charge of the Health Division of UNRRA and be responsible for planning and directing health and medical activities. His duties will require frequent visits abroad to the regional offices and field work. Dr. Sawyer has had long experience in international health activities through his connexion with the Rockefeller Foundation's International Health Division, of which he has been director for nine years. During his service with the Rockefeller Foundation he directed a hookworm campaign in Australia, made investigations of yellow fever in West Africa, carried on research in New York that revealed a method of vaccinating against yellow fever, and negotiated and planned co-operative projects with the health authorities of many countries of both hemispheres.

## AN OUTBREAK OF PUERPERAL SEPSIS DUE TO A SINGLE TYPE OF HAEMOLYTIC STREPTOCOCCUS

### ITS INVESTIGATION AND REMEDY

BY

MEAVE KENNY, M.R.C.O.G.

AND

MARY BARBER, M.D.

(From the Departments of Obstetrics and Pathology of the British Postgraduate Medical School, Hammersmith Hospital)

From 1935, in the obstetric unit of the British Postgraduate Medical School, a carefully conceived and operated routine has obtained good results in the prevention of epidemics of puerperal sepsis. Among 12,283 deliveries, only 19 isolated cases of haemolytic streptococcal infection of the genital tract have occurred, and none of these could be traced to respiratory tract infection of attendants. In 1938 and 1939 not one occurred. One woman has died of puerperal sepsis since the founding of the unit—a non-haemolytic streptococcal peritonitis developing after Caesarean section for placenta praevia in an emergency case which had been examined vaginally by outside attendants; and one has died of lobar pneumonia complicating localized uterine non-haemolytic streptococcal infection.

#### Preventive Routine

Booked cases without septic foci and with intact membranes are admitted in labour to a "clean" suite (D 6), and after delivery are drafted to "clean" lying-in wards (D 3 and D 5). These wards are made up of several 4-bed units. Unbooked cases without septic foci and booked cases with ruptured membranes are delivered and spend the lying-in period in a "suspect" suite (D 4). Vaginal swabs of all such patients are sent for routine bacteriological investigation, and pyrexial cases are removed from this and the "clean" wards to the isolation block. All cases found to have respiratory tract or other infection are admitted, delivered, and nursed in the isolation block of 10 single-bed rooms and attached labour theatre. These cases, too, have bacteriological investigation of the genital and other tracts performed as a routine measure, whether they are febrile or not.

Each suite has a separate nursing staff; the isolation block has its own house-surgeon, who does not enter the other suites. The visiting and resident obstetricians change their overalls before entering each ward and wear masks covering nose and mouth when in the isolation block, when examining women in labour, and in the delivery theatres. All students and members of the staff submit to a bacteriological investigation of the respiratory tract before joining the unit and on return from holiday. Respiratory tract or other infections bar entrance to the unit pending a bacteriological report on the nature of the infection.

Each patient when admitted in labour has a shower-bath and, after shaving, has the vulva and surroundings painted four-hourly with dettol 30% cream until delivery has taken place. In addition, women in the isolation block with upper respiratory tract infections have their hands anointed with the cream. Dettol cream is also used as a lubricant for pelvic examinations and instrumental deliveries; dettol 10% lotion is employed for swabbing the vulva in the early puerperium.

The following is a report of a recent epidemic of haemolytic streptococcal puerperal sepsis that overleaped these precautions. Its investigation and remedy.

#### Case Records

Case 1.—On Jan. 10, 1944, Mrs. E., primipara, was admitted in the first stage of labour to the clean suite D 6. She was delivered 54 hours later by Sister M. and a student and sent on to lying-in ward D 5. On the 12th her temperature rose to 103° F. She was at once transferred to the isolation block. Bacteriological investigation of her lochia showing haemolytic streptococci, she was removed to the North-Western Fever Hospital, and recovered under sulphonamide therapy, as did all the other women involved in the outbreak.

**Case 2.**—On Jan. 13 Mrs. T., primigravida, with a slight cold, was taken in error to the receiving room of D 6, but was transferred very shortly to the "suspect" D 4, as the isolation block was fully occupied that night. Five hours later she was delivered under the close supervision of Sister M. A superficial perineal tear was stitched with silkworm-gut. She was kept in lying-in ward D 4. On the 17th she developed a temperature of 99.4° F.; the routine vaginal swab taken of all patients in this suite showed in her case haemolytic streptococci.

**Case 3.**—On Jan. 14 Mrs. R., primigravida, after 6 hours' labour in D 6, was delivered by Sister M. She, too, had a small tear stitched with silkworm-gut. She was sent to lying-in ward D 3; on the 17th she had a temperature of 102° F. Haemolytic streptococci were cultured from the vagina.

**Case 4.**—On Jan. 17 Mrs. H., primigravida, was delivered in D 6, after a 10-hours stay, by Sister M. On the 20th her temperature was 102° F. in lying-in ward D 5 (in another than the 4-bed room once occupied by Case 1). Haemolytic streptococci were found in her vagina.

**Case 5.**—On Jan. 18 Mrs. W., primigravida, was delivered in D 6, after 11 hours in labour there, by Sister M. and had a first-degree tear stitched. On the 19th her temperature was 99.6° F., and haemolytic streptococci were cultured from her genital tract. She manifested the infection while in lying-in ward D 3, though not in the same 4-bed room as Case 3.

**Case 6.**—On Jan. 23 Mrs. C., primigravida, was delivered in D 6 by Nurse B., after a stay of 8 hours. Dr. P. sutured a second-degree tear and cared for her during a post-partum haemorrhage. While in ward D 3 her temperature was 101° F. on the 25th, and haemolytic streptococci were recovered from the vagina. This is the only infected woman who was not delivered by Sister M.

**Case 7.**—On Jan. 25 Mrs. D., primigravida, was admitted from the ante-natal clinic at term with hypertension and albuminuria. She went into labour in the ante-natal ward and was sent up to the delivery room of D 6, not entering the receiving room there at all. An hour and a half later she was delivered by Sister M., and a tear was sutured by Dr. P. On the 27th, in lying-in ward D 4, she developed a temperature of 101° F., due to a haemolytic streptococcal infection of the genital tract.

### Investigation and Remedy

The bacteriological report on the vaginal swab of Case 1 was known on Jan. 14, and at once nose and throat swabs were taken of the nursing, domestic, and medical staffs of the labour and lying-in wards concerned, and vaginal and nose and throat swabs of the three puerperal women who had shared a 4-bed lying-in ward with Case 1. The nose and throat of the patient herself were also examined. Haemolytic streptococci were not recovered from any of these sites. When the other cases appeared, similar investigations were made, and all proved fruitless. Repeated cultures from the respiratory tract of Sister M. were negative. Late in the course of the epidemic a few colonies of haemolytic streptococci were recovered from the throats of a member of the consultant medical staff, Dr. K., who had not attended any of the affected women, but who had visited all the wards involved: of a nurse who worked in lying-in ward D 3; and of a ward maid of D 3. The dust of the receiving and labour wards was negative; a few colonies of haemolytic streptococci were found in an office attached to D 6 which is used by the medical and nursing staffs. This room was fumigated with formalin vapour at once.

Diligent search for the source of the epidemic went on. The bed-pan- and bidet-sterilizing apparatus in the labour ward as proved relatively effective only, for a test implant of streptococci survived, although streptococci were not found on any utensils that had already been "sterilized" and held ready for use. The apparatus was overhauled, and the steam pressure, upon which its efficiency depends, has been adjusted. It is now satisfactory.

However, an abundant growth of haemolytic streptococci was recovered from the under-rim of the lavatory seat in the receiving room of D 6, through which all but two of the infected women had passed on admission. The lavatory seat is two feet away from the porcelain slab on which all patients admitted to D 6 receive a shower-bath. It was cleaned daily by a maid, using Jeyes' fluid; the positive swab was obtained shortly after such a cleaning had been performed and before its next use. On the discovery of its contamination the room was disinfected with formalin vapour. There have not been any infections since, and the furniture of the room is now

cleansed with pure dettol after each time of use. To strengthen the barrier, each woman now admitted in labour has the vulva painted with dettol cream *before* the parts are shaved or the bath given or the lavatory visited, as well as thereafter.

### Bacteriological Report

In searching for a source of infection for these cases of puerperal sepsis 350 specimens were examined for the presence of haemolytic streptococci. These included nose and throat swabs of staff; nose, throat, and vaginal swabs of contact patients; samples of dust from various sources; plates exposed to the air in labour wards; and swabs from lavatory seats and bed-pans. Lancefield A haemolytic streptococci were isolated from 5 of these specimens—three throat swabs of members of the staff, the lavatory seat in D 6 receiving room, and the dust in the office of this suite. The number of haemolytic streptococci isolated from the lavatory seat was overwhelming. Lancefield G haemolytic streptococci were isolated three times—from the throat of a nurse and from the vagina of two apyrexial patients. One patient had Lancefield C streptococci in the throat.

All the Lancefield A haemolytic streptococci were submitted for typing to Dr. Dora Colebrook and Mr. Maxted, of the Emergency Public Health Laboratory, Ravenscourt Square. We have to thank them both for this co-operation, and Dr. Dora Colebrook for most helpful comment. They reported that the seven streptococci isolated from the cases of puerperal fever all belonged to the same type, provisionally diagnosed as 4/24. Of the other five Lancefield A haemolytic streptococci, the two isolated respectively from the lavatory seat in D 6 and the dust in D 6 office were identical in their reaction with those isolated from the infected women. The streptococci recovered from the throats of members of the staff (Dr. K., a nurse, and a ward maid from D 3) were of different types and not related to the epidemic. None of the three cases in which operative delivery was performed by Dr. K. about this time were infected by the strain she carried, nor was the type carried in the throat of nurse and maid conveyed to any patient in their ward.

### Discussion

The cause of the epidemic is not quite clear. Although the lavatory seat in D 6 receiving room was heavily contaminated with the causal organism, it is difficult to imagine that direct spread took place from seat to patient, and in two cases (Case 2, delivered in D 4 after only a few minutes' stay in D 6; and Case 7, conveyed from the ante-natal ward straight to the labour room of D 6) this was not even a possibility. Unfortunately, immediately this bacteriological report was known the receiving room was closed and fumigated with formalin vapour, so that further investigation of its flora could not be carried out. It is very probable, in view of the gross contamination of the lavatory seat, that other objects in the room, and even the air, contained streptococci. After fumigation streptococci were not isolated from any part of the room. The swab from the lavatory seat was taken from underneath the "plastic" rim, and, although the seat is cleaned daily with an antiseptic, it is possible that the lower surface had been neglected, so that enough organic material remained to permit growth of organisms. In this case it might have acted as a reservoir of streptococci, contaminating the receiving ward and possibly the gowns of patients and nurses. The strongest piece of evidence pointing to this source of infection as the cause of the epidemic is the fact that after fumigation of this ward no further cases occurred. How the seat originally became contaminated is a matter for speculation; it is quite conceivable that it took place through Mrs. E. (Case 1) or an unknown non-febrile carrier before her.

There is no other strong link connecting all the cases. During the two weeks of the epidemic 71 women were delivered in the unit, 28 of these at night. Of the 28 night cases 11 were delivered by Sister M. and 6 became infected. Two of these had not used the contaminated seat. The remaining case was delivered by day and by another hand. She had used the contaminated seat.

The apparatus for sterilizing bed-pans was not entirely satisfactory at the time. It is possible that the spread of infection was aided by this, although once again it is difficult to believe

that direct spread from bed-pans was the cause of the epidemic, as pathogenic organisms were not recovered from any in use.

### Summary

An outbreak of haemolytic streptococcal infection among puerperal women is described. All the 7 cases were infected with the same type of streptococcus. It is suggested that the infection was spread, directly or indirectly, from a lavatory seat in the receiving ward.

## NARCO-ANALYSIS WITH NITROUS OXIDE

BY

C. H. ROGERSON, M.D., M.R.C.P., D.P.M.

Medical Director, Cassel Hospital

Since anaesthetics were first used in surgery it has been common knowledge that during the periods of induction and recovery the tongue of the patient tends to be loosened and expressions are uttered which would ordinarily be repressed. This observation merely bears witness to the truth of the saying, *In vino veritas*. During recent years psychiatrists have made use of this phase of lowered self-criticism and self-control for various purposes. The anaesthetic agents that have been chiefly employed in psychiatry have been the barbiturate group of basal narcotics.

### Narco-analysis in the Twilight State

I first became interested in the possible utilization of the twilight state produced by these agents, in suitable dosage, by the accidental observation at Guy's Hospital that it was exceptionally easy to convey suggestion to patients who were recovering from avertin anaesthesia. The matter was there subsequently pursued with greater precision by Campbell (1938), who recorded a series of experiments using intravenous cyan (soluble hexobarbitone) and summarized the literature then available. Horsley (1936, 1943) has carried on a far wider range of investigations. He has coined the convenient term "narco-analysis" and has been chiefly responsible for the present widespread use of the method.

As with all new techniques, some exaggerated claims have been made for its usefulness. However, it appears to have a definite role in the treatment of certain psychiatric disorders, and has been employed at the Cassel Hospital since 1937.

The effect of the intravenous injection of a soluble barbiturate seems to be to produce a state of temporarily reduced self-criticism in which suggestions are more readily accepted, and in which painful or repressed ideas come more readily to consciousness. This effect is closely comparable to that which may be produced by light hypnosis, but it is achieved without the two main disadvantages of hypnosis—namely, a semi-magical atmosphere and the risk of the development of an excessive, often sexually coloured, dependence upon the hypnotist.

In the treatment of neurosis the method is useful in two types of problem: first, in conversion hysteria, particularly in hysterical fugues, for the rapid removal of symptoms or recovery of memory by suggestion and persuasion under narcosis; secondly, in anxiety neuroses and other disorders in which fairly deep psychological analysis is required, for the rapid access, by free association under narcosis, to repressed ideas and complexes which may lie at the root of the condition. In both types of disorder the use of the drug may produce dramatic results ranging from the vivid emotional recollection of some recent terrifying incident to the recapture of some long-forgotten childhood fantasy.

The method is essentially and principally a time-saving one. It is doubtful whether, in the neuroses at least, results are obtained which could not ultimately have been gained without its use. However, in psychiatry particularly, any method of investigation or treatment which saves the time of physician or patient is of the utmost practical value.

The disadvantages of narco-analysis by means of barbiturates are twofold. There is first the objection, which has recently been brought more clearly to the attention of the medical profession, that the intravenous injection of barbiturate drugs, particularly when it may have to be repeated many times, is not without hazards. This links up with the second objection

—namely, that the method is not as time-saving as one would like. In order to carry it out with adequate safeguards for the patient an assistant is necessary; the patient must be prepared as if for a short general anaesthetic, and resuscitation materials must be at hand. This preparation must be repeated for each injection, although in some cases the progress made at a single session may be very limited.

### The Nitrous Oxide Method

During the past 12 months a way has been found of overcoming these objections by the substitution of inhaled nitrous oxide for intravenous barbiturates as the anaesthetic agent. Experiments with nitrous oxide were begun because many patients and normal individuals spoke of the remarkable feeling of release, of freedom, and of power which they experienced under gas. Such feelings generally point to just that reduction of the normal critical faculties which it is the aim of narco-analysis to achieve.

It was found that a slow induction of analgesia, using a mixture of gas and air gave the best results, and for this purpose the Minnitt obstetrical gas-air-analgesia apparatus proved ideal. This has a number of advantages over the ordinary gas-anaesthesia apparatus. First, the flow of gas is regulated by the patient's breathing, so that there is no waste. Secondly, the patient himself controls his intake of gas and can stop at any moment; fear is thus almost entirely eliminated. Lastly, the apparatus is simple and requires almost no manipulation by the psychiatrist.

The proportion of gas to air delivered by the machine in normal usage is about 45%. This is enough for many patients, but can be increased if necessary by closing one or two of the air-inlet holes with the fingers. With this method it is not advantageous to render the patient unconscious, as it wastes time to do so and is apt to diminish the co-operation of the patient. The best technique appears to be to allow the patient to breathe the mixture until restless movements and some change in the rhythm of respiration herald the approach of loss of consciousness. At this point the patient's own grip on the mask and on the air-hole at the back of it relaxes (as indeed with this apparatus it is intended that if shall do), and the inhalation of gas ceases. The subsequent twilight state, which lasts for a minute or two and which is very easily prolonged by suggestion, is utilized for narco-analysis. About 20 breaths of the mixture usually suffice, and the experiment can be repeated as soon as the effect has worn off.

In practice the method and its intentions are explained to the patient and the use of the apparatus is demonstrated to him. He is shown how the whole process is under his own control, and this at once allays apprehension. He is invited to have a "trial run" without any attempt at psychotherapeutic intervention. After this he is ready to begin.

At first, during the whole of the induction period, gentle suggestions are given that he is becoming relaxed, that painful ideas will come more readily to his mind, and that his thoughts are flowing easily and without restraint. Directly he drops the mask he is urged to express whatever comes into his mind. In the case of a hysterical fugue he is told that he will relive the forgotten incidents, just as would be done under hypnosis or narco-analysis with a barbiturate.

In our experience abreaction and the recall of repressed memories are as vivid and as readily obtained as with any other method, and the time and preparation saved are of course very great. The method has been employed with a considerable number of patients during the past year, of which the two following are representative examples.

### Illustrative Cases

**Case 1.**—A male aged 19; admitted July, 1943. Reason for referral: loss of memory; periodic fugue states in which he wandered away from home after an emotional crisis, usually in relation to some delinquent behaviour. A normal child until the age of 5, when he had rheumatic chorea and his parents were told that he must not be crossed in anything. Subsequently avoided responsibility and punishment because of his "delicacy." First wandered away from school at 14 in a fugue following some minor difficulties there. Had subsequent fugues after failing an examination and after being found out in a series of lies. Three months before admission, after a row with his grandfather, who took a stern and realistic view

of his behaviour, he fell downstairs and was picked up with complete amnesia for the whole of his past life. Concussion was at first diagnosed, but the picture was soon seen to be essentially a hysterical one, and he was admitted to hospital after attempts at recovery of memory by persuasion had failed. Administration of nitrous oxide, using the technique described, produced a dramatic return of memory for the events preceding the fall and for the main events of his past life. Subsequent administration enabled him to recall and relive his activities during previous fugue states, which he claimed had never been recollected. Psychotherapy was then continued along orthodox lines.

Such dramatic recollections and abstractions are very pleasing at first sight, but they do not constitute the principal justification for the use of this method. An experienced and sympathetic psychiatrist can usually resolve a hysterical amnesia of this type by almost any method provided that he has won the confidence of the patient. Nitrous oxide merely provides a simple, quick, and efficient method which may be preferred on this account. Its usefulness is, however, most apparent in cases requiring difficult psychological analysis, where the time factor is even more important and where a rapid resolution of repressed conflicts is very desirable.

The second case belongs to this type. This patient presented a typical severe anxiety neurosis.

**Case 2.**—Mrs. A., aged 32; admitted May, 1943. Reason for referral: feelings of exhaustion and weakness; loss of weight; worry over bowels and food. The symptoms had been present to some extent for about 10 years. The immediate reason for their onset seemed simple and straightforward. She was the child of a financially poor family, and after winning a series of scholarships had had a brilliant undergraduate career at a provincial university and had come with a research scholarship to Oxford. There she found herself, both socially and intellectually, in much deeper waters, and since she had always been used to unquestioned leadership at school and at her own university she reacted with anxiety symptoms. She subsequently married a professor in her own field of work and had three children in very rapid succession. She found difficulty in living up to her husband's family, and the stresses to which she was subjected increased the anxiety symptoms so that a typical vicious circle of anxiety was created. Such a problem is often fairly readily resolved by superficial analysis combined with explanation, persuasion, and re-education. In this case, however, a deeper and much more complex set of factors were speedily uncovered. Behind the difficulties in her married life there lay a pathological emotional relationship with her father, the solution of which was essential to her recovery. Analysis was at first slow and difficult, but the repeated use of nitrous oxide inhalations produced a rapid flow of forgotten associations of a highly painful sexual character. The patient herself repeatedly asked for the apparatus during the process of free association, and learned how to use it without assistance or advice during difficult periods in the treatment. In this fashion a course of analytical psychotherapy which in the ordinary way would certainly have lasted a year was successfully concluded in six months, and the patient was then able to return home.

#### Comment

It seems certain, from our experience, that other methods of narco-analysis could not have achieved similar results without a far greater expenditure of time for therapist and patient. Repeated sessions under narcosis were necessary, and would have been necessary whatever narcotic was employed. One can resolve a hysterical amnesia or obtain an abstraction to a particular traumatic event in one session, but one cannot unravel the trend of events, often spread over a number of years, which go to the evolution of a problem of this type. In such a case the availability of narcosis "on tap" in the consulting-room, ready to be used at any moment in the course of analysis, is a very great advantage. Patients themselves express a strong preference for the nitrous oxide technique, and, where both have been used in a single case, access to hidden mental conflicts is fully as effective with gas as it is with a barbiturate.

#### Summary

The value and limitations of the method of narco-analysis in psychotherapy are briefly discussed. The intravenous injection of a barbiturate has been the method generally employed. Nitrous oxide inhalation is claimed to be fully as effective for this purpose; it is quicker, simpler, and safer, and can be used in the consulting-room at any time during the course of psychiatric treatment.

## Medical Memoranda

### Large Goitre in a Child of 10

The following case history, with a photograph of the patient, may be considered worth publishing.

A girl aged 10, of miserably poor parents from Abu Tig, in Upper Egypt, came to this hospital in November, 1943. She had a history of a gradual enlargement of the neck, and general ill-health, of four years' duration. There was no complaint of dyspnoea or dysphagia.

On examination the child was seen to be wizened, anaemic, and poorly developed. Though alleged to be 10 years old she weighed only 43 lb., the average weight of a child of 6. There was a large, somewhat nodular, fairly firm bilobed mass, obviously a goitre, extending from mandible to manubrium and well beyond the sides of the neck (see photograph). The tumour was freely movable on manipulation and deglutition, and there was no stridor. A number of enlarged subcutaneous veins were observed moving in different directions over the tumour. The circumference of the neck and tumour varied from 18 to 20 inches. The child was found to be suffering from ankylostomiasis, as is usual with some 90% of Egyptian "fellahin." Her haemoglobin was only 60%, and so the ankylostomiasis and anaemia were treated before operation. She also had some dermatitis over the tumour and chest, which can be noted in the photograph; this responded quickly to simple ointments. There were no signs of thyrotoxicosis.

**Operation.**—As there were no facilities for intratracheal anaesthesia the patient was given 2 drachms of paraldehyde per rectum one hour and 1/200 gr. of atropine half an hour before operation. Only a very small amount of open ether was necessary after this premedication, and there was no anxiety over the airway throughout the operation. The usual "collar" incision was employed, and all but a small portion of the thyroid mass was excised. There was no difficulty apart from the number and size of the vessels, and haemorrhage was minimal. A small drain was inserted through a stab wound below the incision, being removed after 48 hours. Convalescence was rapid and uneventful, and the father insisted on removing the child some three weeks after the operation, before any great improvement in the general condition could be expected.

**Examination of the Tumour.**—The growth was in two parts, corresponding to the right and left lobes of the thyroid gland and parts of the isthmus. In appearance it was similar to normal thyroid tissue, but with numerous cysts, varying in size and filled with dark viscid fluid. The right-hand portion measured 6 by 2½ by 2½ in., and the left portion 5 by 2½ by 2½ in. The microscopical report stated, "The appearances are those of a papillary adenoma of the thyroid gland."

My reasons for reporting this case are the large size of the goitre, the comparative brevity of the history, and the youth of the patient. I am indebted to the pathologist and the photographer for their help.

C.M.S. Hospital, Old Cairo.

E. N. CALLUM, F.R.C.S.Ed.

### Varicella and Herpes Zoster: An Experiment

Observations, both clinical and experimental, have repeatedly been made which suggest the existence of a close relationship between the aetiological agents of varicella and herpes zoster. In view of this the following experiment was carried out to find whether convalescent herpes zoster serum would be effective in preventing varicella in varicella contacts. The scale of the experiment was small, but the findings are perhaps suggestive enough to justify publication.

Blood was taken from two herpes zoster patients during the second week after appearance of the eruption. After clotting, the serum was put up in ampoules and stored at a temperature of 4°C. till an opportunity arose for its use (about two months).

On May 31, 1942, varicella developed in a child of 6 years in one of the children's wards in this hospital. Of the other 19 children in the ward, 6 had a previous history of varicella. Of the 13 who had not previously had varicella, 7 were given an

intramuscular injection of 20 c.cm. of convalescent herpes zoster serum on the day after the case arose; the other 6 were used as controls. (Case D. R., with no previous history of varicella, was admitted to the ward in error on June 21. He was given 20 c.cm. of the serum intramuscularly next day.) The results of the experiment are set out in the Table

### Table of Results

Original Case	Age (Years)	Date Serum Given	Date of Varicella	No. of Recurrences
A. O. .. ..	6	—	31/5/42	—
<i>Previous history of varicella—no serum given</i>				
V. C. .. ..	4	—	15/6/42	50
K. E. .. ..	3	—	16/6/42	51
H. P. .. ..	3	—	—	—
M. C. .. ..	2	—	—	—
V. H. .. ..	2½	—	—	—
S. T. .. ..	6	—	—	—
<i>No previous history of varicella—no serum given</i>				
J. A. .. ..	1½	—	23/6/42	100
L. C. .. ..	2	—	12/6/42	100
R. H. .. ..	6	—	—	—
A. C. .. ..	5½	—	15/6/42	63
M. W. .. ..	2	—	19/6/42	106
L. W. .. ..	3	—	—	—
<i>No previous history of varicella—serum given</i>				
J. Y. .. ..	3	16/42	20/6/42	—
P. M. .. ..	11	16/42	—	—
J. D. .. ..	4½	16/42	—	—
D. L. .. ..	2	16/42	—	—
V. W. .. ..	5½	16/42	—	—
C. E. .. ..	2	16/42	—	—
I. M. .. ..	1	16/42	—	—
D. R. .. ..	3	22/6/42	—	—

All the children (except one, J. A.) who subsequently developed varicella were photographed after cropping had ceased, the lesions having been painted with gentian violet to improve visibility. The lesions (except scalp lesions) were counted and the numbers are shown in the Table. It is interesting that the one child (J. Y.) who had no previous history of varicella, and was given serum and developed the disease, was only very mildly affected.

I wish to thank the Medical Director for permission to publish this report.

A. W. ABRAMSON, M.R.C.P. D.C.H.  
A.M.O., West Middlesex County Hospital

## Two Cases of Subcutaneous Rupture of Jejunum : Recovery

The following case records are thought to be interesting enough to merit publication.

### Case 1

A girl aged 11 was knocked down on the evening of May 30, 1940, by a barrow, the handle of which had been thrust against the abdominal wall in front. She complained of abdominal pain which had come on immediately; afterwards she had vomited. When seen the next day the abdomen moved poorly on respiration, and both recti were rigid, with tenderness especially in the lower halves. The child was conscious and did not seem to be suffering from shock. The pulse was rather rapid (120) and slightly irregular, the temperature normal, and respiration 24. Nothing unusual was found in the urine.

On the evening of the history and the clinical signs operation was decided on without further delay—24 hours after the accident it was performed under general anaesthesia consisting of gas-and-oxygen and minimal ether (Dr P. Singer). There was some turbid fluid but no free blood in the peritoneal cavity. A transverse tear involving half the circumference of the gut was found in the jejunum 10 in. distant from the ligament of Treitz; the neighbouring peritonaeum was soiled with flaky exudate indicative of incipient peritonitis. The rent was sutured, and small abrasions situated over the down in the small intestine, together with one on the wall of the transverse colon, were peritonized. The abdominal wall was then closed and a suprapubic drain inserted. The pulse was rapid (150) to 102<sup>b</sup> for 6 days after the operation. The pulse was rapid (150) to 102<sup>b</sup>, and then gradually subsided. Both wounds discharged for 4 days, and there was some post-operative bronchitis. An appropriate dose of sulphates was given intramuscularly at operation and repeated in two days; this was followed by a course of sulphanilamide rectally and by mouth. Graduated feeding by the mouth replaced rectal salines as the condition improved, and was well tolerated. No abdominal distension occurred, and 8 days after operation the child was taking light diet well.

## CASE II

On Dec. 28, 1943, a man aged 22, while attending to a "shaung" machine, was caught between the iron plate and the machine by a double impact which hit him in the back. After the blow he suffered intense abdominal pain, central in position, constant but eased by "stretching" out. There was no vomiting and the spine and skin over the back (where he was hit) appeared normal. After the accident he walked 30 yards to a shelter; at no time did he lose consciousness. During conveyance to hospital by ambulance he noticed pain in the left shoulder for the first time. On admission he

was obviously distressed and in pain, but was only slightly shocked: his face was ashy, cyanosed and respiration was laboured. There was generalized abdominal rigidity on examination, with maximum tenderness in the left upper quadrant, the abdomen in this area the skin was marked by superficial abrasions. The pulse was 64, temperature 97.8°, respiration 20, and blood pressure 120/80. The urine was clear. The diagnosis seemed to rest between ruptured intestine and ruptured spleen.

The abdomen was opened by a left upper paramedian incision. 2½ hours after the accident, under general anaesthesia, using cyclopropane gas, and oxygen through an endotracheal tube by the closed-circuit technique (Dr. D. M. M. Carr). When the peritoneum was incised free blood issued from the peritoneal cavity. The spleen was palpated and found to be unharmed. The intestine was then searched, starting from above, and at a point 12 in. from the duodeno-jejunal flexure the jejunum was seen to be completely torn across, its edges contused, somewhat swollen, and everted. The lumen appeared empty, and except for blood in the neighbourhood there was little soiling of the peritoneum. The mesentery was only slightly torn and the vessels were scarcely harmed (see Fig.).

The open ends of the gut were ligated and invaginated, and a lateral anastomosis was then performed. The mesentery came together well, and was left unsutured. Sulphacetamide (albucid) was applied to the suture line and the abdomen was closed without drainage. Anaesthesia was smooth, and the patient's condition was satisfactory throughout; consciousness was regained in room.

Post-operative intravenous serum given. Stomach suction was maintained by mouth began on the second day—first clear fluids, then opaque fluids (fifth day), and on the eighth soft solids. The pulse, though of good volume, remained around 130/140 for two days, dropped to 100 in the next two days, and then returned to normal. The wound healed well. There were no chest or other complications.

COMMENT

As a rule this injury is said to be the result of a sharp impact, crushing the intestine against the vertebral column, before the abdominal muscles have time to be on guard. In the first case this may be the explanation, but in the second the force seems to have been applied to the back from behind.

In view of the high mortality rate associated with cases of 12 hours' duration—stated to be as high as 70%—the child, who was not operated on until 24 hours afterwards, may be regarded as having made a fortunate recovery.

## A Technique for Episiotomy

In the comparatively rare instance in which this little operation is indicated the following method has been found useful: When the vulva is stretched by the presenting

part a director is passed to lift the rim slightly away from the advancing parts and stitches are then quickly passed, encircling the proposed line of incision (see diagram). Anchor the free ends lightly with artery forceps; draw the looped ends from under the edge of the vulva and anchor with a second pair of artery forceps. As the presenting part crowns (and a perineal tear is seen to be inevitable), draw the looped ends upwards, slightly retracting the edge of the vulva, and make a scissors cut between the loops (see diagram). After the birth and cleansing of the vulva, the wound edges are readily approximated by tying off the stitches. Further stitches can be inserted if necessary. This technique permits of an accurate approximation of the wound edges, and there is no need to give chloroform after the birth to relieve the pain of stitching up. For the sake of clarity the incision shown in the diagram

Borrowash, Derbyshire.

## Reviews

### THE ANTIGONADOTROPIC FACTOR

*The Antigonadotropic Factor, with Consideration of the Antihormone Problem.* By Bernhard Zondek and Felix Sulman, Hebrew University, Jerusalem. (Pp. 185. £53.00 or 16s. 6d.) Baltimore: The Williams and Wilkins Company; London: Baillière, Tindall and Cox. 1943.

This is a specialist monograph whose subject-matter involves both immunology and endocrinology. Many people are familiar with one of these subjects, but there can be few familiar enough with both to be able to read the book with ease. It is not confined to its title-subject, but reviews the literature on the other antihormones, and includes the first publication of a number of the authors' own experiments. The term "antihormone" is given inverted commas throughout because the authors conclude that such factors are not hormones but immune bodies.

When Collip first called attention to the formation of antihormones he suggested that they played a physiological part in the normal bodily economy, but in spite of a great deal of work carried out since that time the hypothesis has little evidence to support it. At present it is undoubtedly true that protein hormones, particularly those of the pituitary gland, when injected into man or animal provoke the production of antihormones which in time considerably diminish the response to successive injections. It is also true that almost all the experimental work has so far involved the use of impure extracts. To-day in America a number of the pituitary hormones have been prepared in crystalline, and presumably pure, form, and it will be interesting to see if these pure preparations also induce antihormone production. If they do, the theoretical interest of the subject will undoubtedly revive, but meanwhile the problem is a purely practical one. So long as clinicians are aware that antihormones are produced by the injection of the pituitary and gonadotropic preparations commercially available, there seems little point in their studying the problem any more closely.

The presentation is clear, though the style is poor. The text is, perhaps inevitably, interrupted by reference to long lists of names and dates; nor has Zondek kept in check his habit of coining terms—to refer to the ovary acted upon by chorionic gonadotropin as the "effector organ" is unnecessary and inaccurate; "gonadotropic-anti-units GAU" and "prolanti-units PAU" abound, and all are in rat units, although international units of chorionic and serum gonadotropins have been in existence now for five years. In spite of the wealth of references, the statement that "pregnant mares' blood gonadotropin . . . is also supposed to be of pituitary origin" is made without any reference, presumably because the majority of workers do not hold this view. Notwithstanding these blemishes the book will prove very useful as a work of reference.

### COMMON SKIN DISEASES

*Common Skin Diseases.* By A. C. Roxburgh, M.D., F.R.C.P. Seventh edition. General Practice Series. (Pp. 454; illustrated. 18s.) London: H. K. Lewis and Co. 1944.

There is no need to emphasize the excellence of a textbook which goes through seven editions in twelve years and has achieved two of those editions and three reprintings since the war began. Perhaps the chief differences between this and the last edition are to be found in the section dealing with industrial dermatitis, which has been expanded, and in the chapter on vitaminoses, which has been rewritten. A new disease seems now to have been added to dermatology, known as "immersion foot," which is a complaint brought on by immersion of the legs and feet for long periods in cold seawater in water-logged boats or rubber dinghies. This must be a very close relation of trench foot, with which medical officers were only too familiar during the last war, but the principle of the local treatment has now been radically changed. Formerly the extremities were kept warm, but it has now been found that very much better results are obtained if the feet are exposed to cool air while the rest of the body is kept warm and comfortable.

Dr. Roxburgh is one of those physicians who have been, fortunate enough, as readers of this *Journal* are well aware, to be entrusted with a supply of penicillin, and he has just had time to include in the present volume a short note on the results obtained from it in dermatology. He says that there is no doubt penicillin will prove a very valuable treatment for certain staphylococcal and streptococcal infections of the skin, and gives hope that syphilis, always considered one of the most refractory and chronic dermatoses, may be controlled by the new drug in a large proportion of cases.

The price of this edition has gone up 2s. to 18s., but one cannot say that this is in any way an excessive increment—in fact it is so small that one might almost think it is a "controlled" price.

### MEDICINE AND THE WAR

*Medicine and the War.* Edited by William H. Taliaferro. Charles R. Walgreen Foundation Lectures. (Pp. 193. 12s.) Chicago: University of Chicago Press; London: Cambridge University Press.

The University of Chicago Press has published a book of medical lectures on war topics given by distinguished workers in each field. The lectures include the subjects of food chemotherapy, malaria, spread of disease by aeroplane transport of insect vectors, shock and blood substitutes, aviation medicine, psychological effects of head injuries, psychiatry, and chemical warfare. Without disclosing secret information the lecturers give a useful account of the problems, well worth reading by medical men and others anxious to know what research is on foot during the war.

The editor of the book, Dr. W. H. Taliaferro, gives an account of malaria. He stresses the part played by immunity, which is often neglected in discussing this disease. The macrophages of the spleen, liver, and bone-marrow play a part in natural immunity; they digest large numbers of parasites, malarial pigment, and red cells containing parasites, removing as many as two-thirds of the parasite population. When acquired immunity is superimposed, the macrophages eat up many more parasites owing to the appearance in the blood of an opsonin, which makes the parasites more easily digested. Dr. C. G. Huff, the parasitologist, discusses the dangers of the spread of disease by aeroplane, and gives an account of the work of the Rockefeller Foundation in eradicating the *Anopheles gambiae* from Brazil, whither it probably came by plane from Africa. In 1938 about 60,000 people out of a population of 70,000 in the Jaguaribe river valley were attacked by malaria. Vigorous efforts in 1939 and 1940 resulted in complete control of this mosquito, and no larvae or adults have been found since September, 1940.

In the chapter on aviation medicine we are told of the physiological changes which occur in a pilot when he makes a sharp turn, as in pulling out of a dive; these include loss of vision and unconsciousness due to the centrifugal force acting on the blood in his head. In the chapter on head injuries there is an account of the effect on a patient whose frontal lobes were damaged as a result of the removal of a brain tumour. He gained a position as salesman for a small firm and was so successful in collecting orders that he was made vice-president of the company; so inspired was he by his success that he soon collected far more orders than could be executed. The firm, to avoid bankruptcy, dismissed him. He lacked the judgment to know when not to sell.

### Notes on Books

*Health Education on the Industrial Front* (Oxford University Press; 8s. 6d.) records the five lectures given at the 1942 Health Education Conference held under the auspices of the New York Academy of Medicine. In the lecture on "Food and Nutrition in the Home and in the Workplace" the data about workers' families are similar to those obtained in this country, and in addition it is stated that observations on clerical and laboratory workers in New York City showed a high incidence of nutritional inadequacy. From 25 to 50% of these persons showed mild but definite lesions characteristic of food deficiencies. A lecture on "Disease and Handicap Detection and Control in Industry" is followed by one on "Mental Problems and Morale in Industry," which gives instructive advice to the industrial physician for the maintenance of high industrial morale. The final lecture, on "Educational Methods and

Control of Accidents in Industry,<sup>1</sup> gives some figures of accident frequency which show that in America, after making due allowance for differences of population, the accident rate from motor traffic and from occupational causes is about twice as great as in this country.

*Atlas of Obstetric Technique* by Dr. PAUL TITUS, is a beautifully produced volume (Henry Kimpton; 36s.). It undertakes to present in pictorial form the subject of modern obstetric technique for both normal and abnormal cases. It also includes a section dealing with sterility. In its purpose it is the obstetrical complement to Bonney's *Operative Gynaecology*, but it compares favourably with this in the excellence of its individual drawings rather than in their selection or arrangement. For example, Section V, dealing with the most important subject of abortions, illustrates well the technique of evacuating a uterus, providing it is anteverted. The necessity for examining the pelvis carefully before operating is overlooked, and were this omission also made by the operator he would perforate the wall of many a retroverted uterus. There is one way to learn how to operate—the hard long road of the apprentice—but that road can be made easier and possibly shorter by an atlas such as this.

## Preparations and Appliances

### APPARATUS FOR INTESTINAL INTUBATION

Dr. J. J. WILD writes from the Miller General Hospital, N.E. 10:

Owing to the unsatisfactory condition of the technique of intestinal intubation at the present time it was decided to try to improve the existing facilities. The apparatus described below has, up to now, given very satisfactory results in the few cases in which I have had the opportunity to use it.

The Miller-Abbott tubes at present manufactured in this country have, in my hands, proved most unsatisfactory. Even when first delivered many faults were found, such as leaks at the point of attachment of the inflation and aspiration nozzles and at the proximal point of attachment of the balloon. Also the bores of the tubes are constricted on occasion, the binding at the proximal point being applied too tightly. The quality of the rubber is too soft, so that the tube tends to collapse when reasonable suction is applied soon after the tube has come into use. I have not found this fault with the American-manufactured tubes, which are constructed of a harder, poorer quality rubber, presumably to avoid this trouble. Apart from these disadvantages I have, I think, overcome many of the inherent disadvantages of tubes used for intestinal intubation, so that the passage of tubes into the duodenum may be carried out with confidence of success whenever it is desired to do so.

#### Description of Apparatus

The apparatus in its present form was manufactured from hospital stock tubing and other sundries easily to hand, and has proved highly satisfactory. A constructional drawing is appended (approximately 2/3 scale) which shows the apparatus to consist of two separate tubes, one of adequate wall-strength to permit of effortless aspiration, the other, small-bored bicycle-valve-type tubing for inflation of the balloon. These are swallowed together and give little trouble so long as they are kept together at the time of passing. In the final development of the tube they will be vulcanized together.

At the point of attachment of the balloon a special easily constructed metal adaptor (A) is incorporated which does not affect the ease of swallowing; this provides attachment for the two tubes, for the proximal end of the balloon (an ordinary contraceptive condom), and for the continuation of the aspiration tube through the collar. Provision is made for a firm grip between metal and rubber, which is carefully bound on with strong thread. Exposed thread is treated with rubber solution to protect it from the contents of the gut.

On the end of the continuation piece of rubber (B) is attached a special metal connexion-piece (C) turned from steel to avoid amalgamation with the mercury. This provides attachment for the balloon proximally and for attachment of the gravity director head (D). This is the most important part of the apparatus and consists of a thin rubber bag taken from the ring or little finger of an old

surgical glove in good condition. This bag is filled with clean mercury expressed through cloth to a weight of 30 to 40 g., though less may be found satisfactory. There is a "dead" space above the mercury, and as little air as possible is permitted to remain when the bag is attached as before-mentioned. Such is the apparatus which I have used several times successfully, no failures having occurred so far.

Should the apparatus come into more general use, I have designed a tube to be made by the commercial manufacturers which will render the technique of intestinal intubation so simple that a highly skilled operator will not be necessary. The balloon will not have to be tied on when renewed but will be pushed on in a matter of seconds where this type of tube is to be used. Also, the metal parts used in my improvised apparatus will probably be eliminated.

The action of the gravity director head is as follows. The mercury acts as fluid ballast which will persistently seek the lowest point, and owing to the thinness of the rubber wall of the sack the mercury, on arriving at a depression such as a sphincter, will pass the end of the sack into the depression and by its weight tend to open the sphincter, allowing the end of the sack to pass together with a portion of mercury until all of the sack together with the mercury has passed the obstruction and pulled with it the remainder of the apparatus. Thus what was previously a problem of feeling a way in the dark has become a matter of merely giving the apparatus its head! Hence the term "gravity director head." This principle can, of course, be easily applied to duodenal intubation for collecting specimens of bile, and as soon as opportunity permits I intend to carry out full clinical trials and publish the results.

#### Technique of Passing the Tube

The patient is told to open his mouth and put out his tongue, which is depressed with a spatula. The tube, dipped in water or lubricated with a non-oily lubricant, is thrown so that the gravity director head falls to the back of the mouth and slides down the pharynx. The patient is instructed to swallow twice and breathe hard. Vomiting may occur but this will not dislodge the tube owing to the weight of the mercury. When the patient has regained control, he is given sips of water and the tube passed down into the stomach. Aspiration is started at this point with about 150 c.cm. metal syringe. Sufficient tube is then swallowed (about 30 inches), if possible with the patient on his right side and with the foot of the bed blocked up as high as possible. If desired the patient may be carried on his right side to the theatre, and the journey will probably facilitate the passage of the director head into the duodenum. If facilities are available the patient is radiographed in this position in bed, and if the tube is found not to be in the duodenum he is lifted high by his buttocks on his right side and rotated and shaken to facilitate the passage of the tube under the action of gravity. This manipulation is only necessary when the tube will not pass easily. If difficulty is experienced, a little watery barium sulphate may be put into the stomach in order to see the position of the outlet of the stomach as compared with the director head.

As a rule, I think the tube will pass easily provided enough is swallowed. Often, if an immediate success is not obtained, repeated aspiration of the stomach will restore its tone and the tube will be found in the duodenum later if the patient is kept on his right side. Manipulation and x-ray control need only be used when it is urgently required to pass the tube.

So far I have had difficulty with one case only (paralytic ileus following gastro-enteritis) and have had to resort to manipulation and x-ray control. No failures have occurred so far (six cases). With experience I hope to evolve a technique which will give very few, if any, failures.

I have taken out provisional protection of the gravity director head with a view to preventing anyone restricting the use of the apparatus by patenting it. It may be possible to get the two metal connexions made as in the improvised tube described, should the demand be great enough, so that anyone interested could try the tube out.

I am indebted to my colleagues at the Miller General Hospital for their kind help in many ways.

### NEW CHOLECYSTOGRAPHIC AGENT

Burroughs Wellcome and Co. announce the issue of preparations of "pheniodol," a new cholecystographic contrast medium for oral administration. Recent clinical trials (*British Medical Journal*, 1943, 2, 674; *Brit. J. Radiol.*, 1944, 17, 60) have shown this substance to possess important advantages as regards effectiveness and tolerance. "Wellcome" brand pheniodol, the pure compound, is available in bottles of 25 g. "Wellcome" brand pheniodol meal presents the substance combined with wetting and flavouring agents which enable an easily taken and palatable suspension to be conveniently prepared: it is issued in tubes containing 4.5 g., equivalent to 3 g. (the normal adult dose) of pheniodol available singly and in cartons of 6 tubes.

## BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JUNE 17 1944

## MEDICAL SERVICES FOR THE WESTERN FRONT

The attack on Western Europe has opened, and the share of the medical profession in this has been graphically illustrated in the daily press. Wherever the fighting man goes the doctor goes with him, and shares many of his risks so that he can offer him the indispensable first aid and what is termed "life-and-limb surgery." The nature of his medical training and the free circumstances of the peacetime practice of his profession develop a sense of responsibility and adaptability that serves the British doctor well in war, whether he falls through the air with the paratroops or crouches beside the wounded soldier on the sand of the desert or of the Normandy beaches. So that the wounded and disabled may receive complete medical and surgical aid at the shortest time after injury a vast organization is necessary, and this is a fitting moment to give some account of the medical organization that has evolved out of more than two years' planning for D Day.

There are now over twenty varieties of medical units accompanying the Forces. Many of these varieties are subdivisible into types: for example, there are various types of field ambulances, such as light field ambulances, parachute field ambulances, and air-landing field ambulances. There are various types of field surgical units, from special teams for neurosurgery, maxillo-facial surgery, and chest surgery, to the standard field general surgical unit for reinforcing casualty clearing stations, and, in conjunction with field dressing stations and field transfusion units, for forming advanced surgical centres. There are a large number of field dressing stations, field transfusion units, casualty clearing stations, general hospitals, hospital ships, hospital carriers, and specially equipped L.S.T.s (Landing Ships, Tanks). These are only some of the types. In all there are more than 400 medical and dental units, including a special unit provided by the British Red Cross Society and Order of St. John of Jerusalem. These units have establishments providing specialists as required in every branch of medicine and surgery, nursing orderlies, dispensers, cooks, drivers, etc. The vast majority are mobile, and all have been thoroughly trained; some have wide experience of active operations. These units are allotted to formations according to their needs. Divisions are accompanied by field ambulances, field dressing stations, and field hygiene sections; corps by field dressing stations, casualty clearing stations, general hospitals, and advanced depots of medical stores. G.H.Q. has at its disposal an imposing array of all types, including general hospitals of 600 and 1,200 beds whose staffs include specialists in every branch of medicine and surgery, including dentistry. Finally, divisions, corps, and armies have their own medical staff officers, supervised and controlled by the Director of Medical Services of the force, assisted

by the strongest possible teams of experienced consultants, advisers, and administrative officers.

In the United Kingdom the Ministry of Health, through the Director-General of Emergency Medical Services, has provided tens of thousands of beds staffed and equipped to deal with all types of casualties. Special hospitals have been set apart as casualty clearing stations, others as base hospitals. Military and civil ambulance trains and fleets of ambulance cars, including cars of the British Red Cross Society, convey casualties from ports and airfields to the casualty clearing hospitals (transit and port hospitals). Naval, Army, and civilian staffs man the ports to unload patients from L.S.T.s, hospital ships, and hospital carriers to ambulance trains and ambulance cars. These ambulance trains carry drugs (including penicillin), dressings, food, and other comforts. Special arrangements have been made for notifying next-of-kin: as soon as the patient is admitted to a base hospital a card giving all details is dispatched.

A heavy load rests on those responsible for such an intricate system of essential services. We may recall that the German Army was brought almost to the point of capitulation on the Russian front owing to a breakdown of the medical organization under winter conditions. In the framework provided by organization the individual doctor, and teams of doctors and surgeons, bring their technical skill to the aid of the individual sailor, soldier, and airman. No matter what the type of military operation or the conditions under which it takes place, the principle controlling the handling of sick and seriously wounded in the forward zone is rapid collection and evacuation to an appropriate surgical centre. The main links in the channel of evacuation are regimental aid post, advanced dressing station, field dressing station, casualty clearing station, and general hospital at the base. At the regimental aid post adequate first aid, including the administration of morphine and sulphonamide, and measures for the treatment and prevention of shock, is carried out. At the advanced dressing station patients are divided into three groups: (1) those in need of urgent resuscitation before they can be evacuated to the surgical centre; (2) those suffering from severe wounds that require urgent surgery; and (3) all other patients. Group 1 patients are evacuated to the divisional field dressing station, which is never more than a short distance away and has all the equipment for resuscitation. After resuscitation these patients are sent to an advanced surgical centre if they need urgent surgery, or, if they are fit for evacuation, to a casualty clearing station. Group 2 patients are sent direct to the advanced surgical centre from the field dressing station. The advanced surgical centre may be at the casualty clearing station. But if the distance between field dressing station and casualty clearing station is great an advanced surgical centre is formed nearer the forward troops by the attachment of one or more field surgical units and field transfusion units to a field dressing station. From the advanced surgical centre, if a separate centre has been formed, patients are evacuated to the casualty clearing station. Group 3 patients are evacuated direct from field dressing station to casualty clearing station. In effect this system of evacuation, though it sounds compli-

cated, means that all casualties are sent back to a casualty clearing station, but that facilities are available for preliminary urgent treatment and life- or limb-saving surgery further forward on the line of evacuation. Routine surgery is not carried out in the foremost medical units because they are not normally in a position to provide adequate post-operative care and nursing. A balance has to be struck between the sometimes conflicting claims of early surgery and evacuation. From the casualty clearing station patients are transferred to general hospitals, either the smaller hospitals with the field force or the larger units at the base.

Evacuation by sea must have special consideration. In the absence of suitable ports, specially equipped L.S.T.s with a staff of doctors and nursing orderlies on board, hospital carriers reinforced by surgical teams, and, later, hospital ships, will be used. After receiving adequate first aid and life-saving surgery casualties will be embarked on these craft by water ambulances, D.U.K.W.s, and other small craft. Plans have also been made for large numbers to be evacuated by air when suitable facilities are available on the Continent. The R.A.F. are providing a ground organization at aerodromes, both in the theatre of operations and at home, for the care and accommodation of patients from the time they are handed over to them by the Army in the theatre of operations until they are taken over from them in the United Kingdom.

That, briefly, is the normal procedure. But under the conditions which obtain during an assault from the sea on a strongly defended coast this procedure has to be modified. In the early stages treatment of the wounded consists of adequate first aid similar to that already described. Further treatment will consist of "life-and-limb" surgery and measures to combat shock and sepsis. The organization on or near beaches consists of beach dressing stations, advanced dressing stations, and advanced surgical centres. These units follow close behind the assaulting troops and establish their special centres in a few hours. Supplies of blood products for transfusion are maintained by a special organization based initially on the Army Blood Supply Depot in England. In the early stages all patients are evacuated to the United Kingdom as quickly as possible. All that can safely be done on the spot is done. But definitive surgery must await suitable conditions, such as adequate facilities for operating at a reasonable distance from the noise of battle, and arrangements for adequate post-operative treatment, which includes rest and good nursing. Casualties fit for evacuation are transferred from shore to ship by D.U.K.W.s, which can proceed from the dressing station across sands and sea to the L.S.T.s waiting off-shore. These D.U.K.W.s can be driven straight into the L.S.T.s. The interval between "life-and-limb" surgery and "definitive" surgery is one in which gas gangrene and sepsis have to be prevented or controlled. One step that has been taken is to provide supplies of penicillin on the beaches, on L.S.T.s, on hospital carriers, and on ambulance trains; detailed instructions have been issued regarding dosage and records to be kept. Suitable cases will be given 100,000 units of penicillin intramuscularly before leaving the advanced surgical centre or casualty clearing station. Maintenance doses of 50,000 units at intervals of about five hours will be given until the patient

reaches the surgeon in the transit or port hospitals. In addition to penicillin, whole blood is available on L.S.T.s and hospital carriers. On arrival at United Kingdom ports patients are rapidly sorted by experienced surgeons into two categories. Those requiring immediate treatment will be sent to near-by hospitals already set apart and ready; the remainder will be dispatched by civil or military ambulance train (staffed by doctors, nurses, and orderlies) to E.M.S. transit hospitals located within a couple of hours' train journey. At these transit hospitals civilian surgical teams, reinforced where necessary by Army surgical teams, carry out all urgent surgical measures. From these hospitals patients, when fit to move, will be dispatched to base hospitals (E.M.S.) all over the United Kingdom, and in due course will be sent to military convalescent depots for rehabilitation and hardening to fit them once more for active service.

At this turning-point in our history the men of the United Nations are grappling at close quarters with the enemy, and it is natural that our attention should be focused on measures for treating the wounded. Of no less importance—indeed of greater importance—are all those measures comprehended under the term "preventive medicine." Many a general has been defeated by bad sanitation and by ignorance of the cause of disease. The fortunes of war turn ever more closely on the good hunting of the scientist in the laboratory—and, from the medical standpoint, especially the laboratory of the bacteriologist.

### THE ENGLISH DISEASE

At the beginning of the seventeenth century doctors took note of a new disease, common in the South-West and popularly known as the rickets. Milk was at this time, according to Drummond,<sup>1</sup> giving place to bread in the national diet. Whether because of the frequency of rickets in England or because the earlier descriptions by Whistler, Boott, and Glisson were of English cases, Europe called it the English disease. In 1650 Glisson and his colleagues of the College of Physicians reported on the clinical aspects of the disease in a historic treatise.<sup>2</sup> The latest addition to the long enlightening literature takes the form of a report on the incidence of rickets in wartime, presented by the British Paediatric Association at the invitation and with the co-operation of the Ministry of Health.<sup>3</sup> The lack of uniformity in age studied and in selection of cases in the pre-war surveys in London, Manchester, Newcastle-upon-Tyne, and Glasgow, summarized in this report, makes comparison difficult, but the question how far war conditions may have checked the recognized decline of rickets in pre-war years receives a negative answer. It may be pertinent to note that for "wartime" could be written (though a neat portmanteau phrase for it is lacking) the time when once again milk is taking its place in the diet, particularly of pregnant women.

The report reads like an epitaph on clinical rickets, at least in Southern England. Rickets is defined not as a clinical syndrome but as a metabolic or nutritional dis-

<sup>1</sup> Drummond, J. C., and Wilbraham, A., 1939, *The Englishman's Food*.

<sup>2</sup> Glisson, F., 1650, *De Rachitide*.

<sup>3</sup> Ministry of Health Reports on Public Health and Medical Subjects No. 92. H.M. Stationery Office, (9d.)

order "characterized by imperfect calcification of growing bone." The criterion for diagnosis was detection of this imperfectly calcified bone in an x-ray picture of the left wrist. Of the 5,283 children investigated in the early months of 1943 in twenty-two centres in the British Isles and one in Dublin, 106 showed signs of rickets in the opinion of two out of the three examining radiologists. In Great Britain, of 3,328 children aged 3 to 12 months 17 showed active and 56 healed or healing rickets, and out of 1,490 aged 12 to 18 months there were 3 active and 7 healed, rates of  $2\frac{1}{2}\%$  before 6 months and 4% during the first year. In Newcastle-upon-Tyne, Manchester, Leeds, and Sheffield the rate among 504 examined before 1 year old was 10 to 12%. Clinical evidence of active rickets was present in 604 out of 4,818 children in Great Britain at ages 3 to 18 months, the proportions varying from none at St. Albans and Watford to 61% in Sheffield. The most important clinical sign was taken to be craniotables at 3 to 4 months, enlargement of costo-chondral junctions at 6 months, and of the epiphysis at the wrist at the end of the first year. Unfortunately for the value of these signs only 32 of the 604 so diagnosed showed radiological signs, while of the 4,214 clinically normal, 48 showed radiological signs. Correlation between clinical and radiological cases was poor. Biochemical tests, performed at some centres, are not recorded, and it would be interesting to know how far babies with a raised blood phosphatase would form another group and how far clinical, radiological, and biochemical rickets occurs in the same case.

Owing to the small number of cases of rickets diagnosed, information about the type of feeding and the amounts and kinds of vitamin D additions to the diet proved too much even for the virtuosity of Dr. Percy Stocks, so ably displayed in the general analysis of the collected observations. Nevertheless the report concludes that rickets, while more common in the artificially fed, may be expected also in the breast-fed baby, and that there is scope for better prophylactic measures and more extensive use of the Government's cod-liver oil. The British Paediatric Association and those who helped in this careful survey deserve congratulation. The report has drawn attention to the difficulties in the diagnosis of rickets when cases of florid type are scarce, and it will provide a good basis for comparison with any future surveys.

Two lines of thought are started by the reading of this report. First, what is the precise importance to the health of the community of "imperfect calcification of growing bone"? A recent paper<sup>4</sup> from Prof. Park's Clinic at the Harriet Lane Home gives the results of histological study of the middle ribs in 230 consecutive necropsies in children between the ages of 2 and 14 years dying from all causes. Of these 23% showed slight, 18.7% moderate, and 4.8% advanced, rickets—a total of 46.5%. The percentage was greater among those dying of illness lasting less than 14 days. In 5 cases at most were changes noted in a radiograph. The authors doubt if slight degrees of (histological) rickets interfere with health or development. Accepting the definition of rickets as a disease characterized by imperfect calcification of growing bone, it seems certain

that rickets was present in many more cases in the British Paediatric Association's survey than were apparent in x-ray pictures of the left wrist. How far does histological or radiological rickets matter? Here is a problem to stretch the pia mater of an apostle of positive health. The second thought is of thanksgiving for the good fortune of the British Isles, where the importance of clinical, radiological, and histological rickets can form the subject of argument at a time when so large an area of the populated world is faced with the reality of gross and unmistakable nutritional disease. The English disease bids fair to end as the European disease.

### RESPONSIBILITY FOR CLEAN MILK PRODUCTION

When the Minister of Agriculture, with the acquiescence of the Minister of Health, seeks the transfer to himself of statutory powers relating to the prevention of disease of milk-borne origin it is well to bear in mind the functions and fundamental purposes of the respective Ministries. In all matters affecting the public health, and for all measures in State medicine authoritatively taken for the prevention of disease among human beings, the Minister of Health has been and must remain responsible. Where primarily the administration of an Act is placed upon local authorities the Minister concerned must see that they exercise their powers and duties or, in their default, that they are superseded by a major local authority, or, in the last issue, by the central authority ultimately responsible. Failure is an affair not merely of local but of central government also. The Minister of Agriculture recognizes this, but his answer in the debate on the second reading of the Milk and Dairies Bill on May 19 was a *non-sequitur*. He said that the whole problem had radically changed since 1926, when these powers were originally entrusted to the local authorities. The intention stated by Mr. Hudson that he and the Minister of Health will be jointly responsible for making regulations for the control of milk supplies does not necessarily imply a joint responsibility for enforcing them.

The battle for clean and safe milk—in which the Board of Agriculture was not conspicuous for its zeal—began and bore fruit long before 1926. It is true that progressive dairymen, led by the Institute of Research in Dairying, Reading, and by local agricultural committees, have done much to rationalize and simplify methods and requirements since that time. The problem has changed, but has changed largely because of the comparative success which has attended the efforts of the most zealous local authorities and their officers. Not so long ago (but long before the date given by Mr. Hudson), when the infant death rate was three and four times what it is to-day, medical practitioners and medical officers of health were agreed that for a large part of this mortality infected milk was to blame. In the industry with which the Minister of Agriculture is identified, and to which public attention was then directed, investigation showed intolerable conditions in respect of premises and practice. To a considerable degree, due largely to the activities of local authorities whom it is now sought to supersede, these evils have been mitigated. Milk, it was

<sup>4</sup> Follis, R. H., Jackson, D., Eliot, M. M., and Park, E. A., *Amer. J. Dis. Child.*, 1943, 66, 1.

found, was grossly fouled on the farm, from uncleanly cows, in insanitary cow-sheds, in unsuitable and ill-equipped dairies, by the ignorant practices of cowmen and dairy hands, in transport to the wholesaler, from him to the retailer, and again by the retailer and in the home of the consumer. Sanitary inspectors and health visitors were trained to deal with these evils and to instruct in the hygienic handling of milk whether at the farm or during transit, and the local authorities were armed with statutory powers to enforce compliance. The veterinary inspection service, of which Mr. Hudson is so rightly proud, had its local origin in these efforts, and initially was brought into being by the major health authorities at the suggestion of medical officers of health. The reduction of infection of infants by cows' milk was partly responsible for the decline in infant mortality which, during the last half-century, rewarded the efforts of local authorities and their officers. Tuberculosis, typhoid fever, scarlet fever, diphtheria, and other diseases, in addition to the diarrhoea of infants, may in a variety of ways be milk-borne, and have each called for preventive measures and been dealt with under statutory powers for inspection of the milk supply which have served their purpose but are now to be split and redistributed. The health officers, to whom they owe their origin, are to be deprived of these slowly evolved powers over milk production, which, it appears, are to pass into the hands of veterinary officers, who are not primarily concerned with human diseases or with the preventive steps appropriate for the control of most of them. The M.O.H. will still be responsible in theory for the prevention of these diseases, but in practice he will enter the field only after the damage has been done. This disjunction of responsibility is comparable to the larger disorganization which the proposals for a comprehensive medical service will involve in other spheres of medicine and public health.

Under an illusion that the Ministry of Agriculture is equipped with the means and the staff for doing what some local authorities, for reasons well understood, have failed to do, most of the M.P.s who spoke in the debate seemed to be willing to hand over to that Ministry responsibilities which it cannot discharge. It is no reflection upon the veterinary inspectorate of the Ministry of Agriculture to say that neither by their numbers nor by their training can they replace in this field of preventive medicine the M.O.H. and his staff, trained in the technicalities for control of disease in man and constantly present in the localities where the dairy farms are situated. No one more than the Public Health Service can welcome the veterinary inspector's efforts to improve, both in health and in quality, the "stock" which are his care, but there is confusion of thought in the failure to distinguish this province of veterinary medicine from that of preventive medicine concerned to control the conditions, at the source as well as at the periphery, under which milk becomes a dangerous vector of disease to human beings.

The main reason given for the transfer of the responsibility for inspecting premises, equipment, and methods of milk production is the neglect or incompetence of defaulting authorities and their officers. Because of the failure of some authorities and of local benches of magistrates to do their duty all the machinery of supervision by

the greater number of local sanitary authorities is to be scrapped, ostensibly to place it in more efficient hands. The weakness of this argument becomes plain when the inadequacy of the staff possessed by the Ministry of Agriculture to deal with the vast volume of work hitherto performed by local authorities is considered. How do the numbers of veterinary officers at the Ministry compare with the army of sanitary officers throughout the country engaged in an endeavour to secure proper conditions in the production as well as the distribution of clean, wholesome, and safe milk? Are trained veterinary practitioners, diluted by a lay inspectorate, to be engaged in sufficient numbers to replace the sanitary inspectors whom it is proposed to withdraw from this work but who cannot be cut down in numbers because of their other local duties? The Ministry of Agriculture should concentrate on the improvement of stock, the raising of healthy cattle, and the care for dairy produce and milk marketing: the Minister of Health should continue to see to it that whoever undertake inspection they shall conform to his requirements for the protection of the public health. The powers hitherto vested in local health authorities are a legacy from generations of experienced hygienists. If it is established that smaller sanitary authorities are hindered in their work by local influences, the remedy is to enlarge the administrative area for this and other functions of local government.

### THE MINISTER REPLIES

The news that the Annual Representative Meeting to be held in July has been postponed at the request of the Government was received by most doctors with mixed feelings. But we rested securely on the understanding with the Ministry of Health that a Bill would not be brought before the House of Commons until full opportunity had been given to the profession to formulate its policy, and to make representations on a proposed legislation. The Minister of Health, however, gave replies to questions in Parliament last week which suggest that this understanding is not bilateral. When on June 8 Dr. Howitt reiterated a question put two days before by Sir Ernest Graham-Little in the following words:

"In view of the postponement of the Annual Representative Meeting of the British Medical Association at the request of the Government, will he give an assurance that legislation on a National Health Service will not be introduced by him until after negotiations have taken place between him and the medical profession, bearing in mind that under its constitution only the Representative Body of the Association can determine the policy of the B.M.A.?"—

Mr. Willink's reply was as follows:

"My hon. friend will appreciate that I cannot give an assurance quite so absolute as he suggests. It is still my wish to have full discussions with the profession before introducing legislation, and I see no reason why I should be prevented from doing so by the delay which will be caused by the profession's inevitable postponement of its conference."

The last fifteen words of the Minister's reply convey an impression which, in the interests of accuracy, it is desirable to correct. The B.M.A. was requested by the Minister of Health to postpone the meeting of the A.R.M.<sup>1</sup> So let it be clear that in this case the profession has had to act on Government instructions. The B.M.A. is compelled by circumstances to postpone its deliberations and for the

<sup>1</sup> See letter from Ministry of Health, *British Medical Journal*, May 27, 1944, p. 727.

time being to remain in ignorance of what the policy of its members in relation to the White Paper proposals is, or, as the Minister well understands, the Representative body alone has the power to make policy. As the Minister of Health has been forced to impose this delay upon us it was taken for granted that he would impose a delay upon himself and his Department in accordance with the understanding that has prevailed between the Ministry and the Association in this matter. But his answers in Parliament last week raise a doubt whether this understanding still exists.

### SPANISH MEDICINE

The Prime Minister's recent references to Spain provide an occasion for reflection on the history and present condition of medicine in that country. Almost exactly 100 years ago an English traveller of exceptional discernment described<sup>1</sup> among other characteristics of the contemporary Spanish scene the low standard of medical education and practice, the menial position of the medical profession, and the hostility of Church and aristocracy to progress. He asked: "Can it still be wondered . . . that their textbooks and authorities should too often be still Galen, Celsus, Hippocrates, and Boerhaave?" adding that "the names of Hunter, Harvey, and Astley Cooper are scarcely more known among their M.D.s than the last discoveries of Herschel." That Spanish medicine should have lagged so far behind is remarkable when one considers the important part played until the thirteenth century by Spain, and especially by the School of Translation at Toledo, in the rediscovery of Graeco-Roman and the transmission of Arabic medicine. In succeeding centuries the darkness is hardly relieved except by Miguel Servet (Servetus), who, bold enough to question Galen but not bold enough to face the ecclesiastical music, fled from Catholic Spain to Calvinistic Geneva, only to perish a victim of fanaticism equally ruthless in its opposition to truth and light.

There are evidently some in Spain who feel that their country does not receive a just recognition in foreign medical histories. Thus, the translator of the Spanish edition<sup>2</sup> of the standard English-language work found it necessary to add a 103-page appendix on the history of Spanish medicine. Similarly, a Spanish edition<sup>3</sup> of a popular English history of surgery is amplified by a 54-page appendix on "Surgery in Spain." It must be confessed that a reading of these appendices does little to encourage the view that important Spanish contributions have been overlooked. Yet in the Arts and those other fields of human endeavour by which a nation's progress is measured Spain occupies a sure and important place, and those Spanish medical men who have in recent years found the opportunity to work in clinics and laboratories in Britain and the Americas have shown no lack of scientific talent and aptitude. The reason for this poverty of medical science in a nation whose natural genius cannot be doubted must surely be sought in the anachronistic survival of that spirit of authoritarianism which is the mortal enemy of experiment and discovery.

In a search for significant Spanish contributions to the body of medical science it is necessary to turn to one who died only ten years ago in Madrid—Santiago Ramón y Cajal. Even Cajal<sup>4</sup> lamented that Spain owed almost all

it had of science and technology to other countries. In a paper<sup>5</sup> read recently in Spanish at the newly founded Instituto Español in London convincing reasons were given for regarding Cajal as the most illustrious Spaniard of the last century. Without belittling the importance of the arts, of philosophy, and of religion, it is not by these paths, but through science that Spain must find her salvation in the twentieth century. The layman may find it difficult to appreciate the greatness of Cajal's work, which was in the domain of fundamental biological science and did not result in those practical applications which attract popular interest and acclaim, but apart from the direct value of his work, it would be difficult to overestimate the indirect influence of Cajal on Spanish thought. He opened the eyes of many Spaniards, who, then and since, first saw beyond authoritarian barriers the more spacious world of scientific inquiry, criticism, and objectivity, and to them his memory remains an inspiration which forms a link between those in exile and those at home. For the first time medical scientists of other countries found it necessary to learn Spanish in order to follow new discoveries in the original. The many honours which were showered upon Cajal from abroad at a time when the national prestige of Spain was at its lowest ebb had an important effect on the public and official attitude to science. It is interesting to speculate upon what would have been Cajal's view of the position of Spain in the present world-wide conflict. Perhaps the answer may be found in his own words<sup>4</sup>: "In the democratic State all liberties are sacred except one—the negation of liberty. And all rights are legitimate except this—the mental deformation of future citizens. We respect as sacrosanct the precious germs of reason, for they belong not to us but to God."

There is evidence that the values for which Cajal stood have not been entirely extinguished in the Spain of to-day, and recent British visitors have spoken with particular enthusiasm of the research<sup>6</sup> on nutritional deficiencies which is being undertaken in the institute at Madrid directed by Prof. C. Jiménez Díaz. Spanish has not hitherto been regarded as a medically or scientifically important language, but in Argentina, Mexico, Chile, and elsewhere in the Spanish-speaking world active centres of medical investigation exist or are developing, and it seems not unreasonable to suppose that Spanish will in the future achieve an important position not only as the language of saints and soldiers, of poets and philosophers, but also as a medium for the communication of discoveries in medicine and other scientific fields.

### THE HALF-YEARLY INDEXES

The usual half-yearly indexes to the *Journal* and to the *Supplement* have been printed. They will, however, not be issued with all copies of the *Journal*, but only to those readers who ask for them. Any member or subscriber who wishes to have one or both of the indexes can obtain what he wants, post free, by sending a postcard notifying his desire to the Accountant, B.M.A. House, Tavistock Square, London, W.C.1. Those wishing to receive the indexes regularly as published should intimate this.

Mr. Desmond MacCarthy, LL.D., will deliver the Lloyd-Roberts Lecture at the Royal College of Physicians of London, Pall Mall East, on Tuesday, July 11, at 4.30 p.m. Subject: "Psychology in Literature."

## THE STRENGTH OF PLEXAN

The method of manufacture of 'Plexan' retains in this liver extract not only the anti-anaemic factor, but also the vitamin B<sub>1</sub> factors necessary for certain cases of macrocytic anaemia.

Microbiological assays of 'Plexan' for some of the factors in the B<sub>1</sub> group give the following average figures per cc.:

Riboflavin	.....	100 micrograms
Nicotinic Acid	.....	1200 "
Pyridoxin	.....	10 "
Pantothenic Acid	.....	400 "
Biotin	.....	0.25 "

Apart from its value in the treatment of pernicious anaemia, 'Plexan' is also of major importance for the cases of macrocytic anaemia of more complex aetiology.

## PLEXAN

BRAND OF  
LIVER EXTRACT FOR INTRAMUSCULAR INJECTION

2 cc. ampoules in boxes of 6 and 36. 12 cc. phials.

GLAXO LABORATORIES LTD., GREENFORD, MIDDLESEX. BYRON 3434

### A simple and accurate Tuberculin Skin Test

Tuberculin Diagnostic Jelly A. & H. provides a skin test free from untoward local or constitutional reaction. The use of this jelly has the following advantages: freedom from pain and injury to the skin by injections, scarification or rubbing; comparative speed of application; simplicity, in that the test can be carried out without help; sharply limited area of reaction owing to the prevention of spread of tuberculin on the surrounding skin; freedom from risk of infection; the jelly keeps indefinitely; and comparative cost. (See report *B.M.J.*, p. 531, April 15, 1944)

It is available in tubes 2 gm. (20 tests) 7/6, 5 gm. (50 tests) 12/6

## Safer Pregnancy and Puerperium

Investigations carried out in London<sup>1</sup>, involving a study of the records of over 5,000 pregnant women, showed that there was a dietary deficiency of Vitamins A, B<sub>1</sub> and C in about 50 per cent. of cases, of calcium in 70 per cent., and of iron in 98 per cent.

After the provision of supplements containing adequate amounts of Vitamins A, B complex, C and D, with calcium, iron, iodine, manganese and copper, the following significant results were noted:—

*Among 1,530 primigravidae the toxæmia rate was 27.1 per cent. as compared with the rate of 31.7 per cent. in a control group of 1,512 primigravidae not receiving*

*the supplement. Based on an annual birthrate of 600,000, this represents a possible reduction of 10,000 cases of toxæmia per annum by the use of a pre-natal diet adequate in vitamins and mineral elements. Noteworthy, too, was the effect on the new-born infant as shown by a definite reduction in the number of premature births.*

Similar results obtained by investigations at the Toronto General Hospital<sup>2</sup> showed that a good, or supplemented, pre-natal diet resulted in better health for the mother, a lower incidence of toxæmias, miscarriages, premature births, or still births, with a decrease in the morbidity and mortality of the infant during the early months of life.

### PREGNAVITE—a multiple supplement

Pregnavite, the first preparation to contain vitamins and mineral salts in correct amounts and proportions to meet the requirements of pregnancy, is the most convenient and economical means of supplementing the dietary of the expectant and nursing mother.

<sup>1</sup> *Brit. Med. J.*, 1942, 2: 77.

Pregnavite in recommended doses supplies, at time of manufacture, approximately:—

Vitamin A	4,000 i.u.	Calcium	350 mg.
Vitamin B <sub>1</sub>	200 i.u.	Phosphorus	550 mg.
Vitamin C	400 i.u.		
Vitamin D	300 i.u.	Available Iron	12 mg.

<sup>2</sup> *J. Nutrit.*, 1941, 22: 515. *Canad. Med. Ass. J.*, 1943, 48: 1507 & 1508.

Further particulars of Pregnavite Tablets gladly sent on request. Vitamins Ltd. (Dept. B.P.N.1), 23, Upper Mall, W.6.

# HYPERTENSION

A combination of phenobarbitone with theobromine has become the standard treatment for the relief of symptoms associated with hypertension.

\* 'Theogardenal' brand theobromine and phenobarbitone tablets are backed by a long experience in their manufacture, 'Theogardenal' brand being one of the first British preparations of this type to be made available. Over a period of ten years it has proved its worth and supported the claims we make for it.

## MEDICINE IN FREE CHINA

BY

WILDER PENFIELD, C.M.G., F.R.S., Hon.F.R.C.S.

*Professor of Neurology and Neurosurgery, McGill University,  
Montreal*

The people of China were turning away from their own ancient forms of medical practice at about the time this war broke out, and the Chinese Government had embarked upon a policy of rapid increase in the number of university medical schools. Instead of expansion, however, the loss of the seaboard cities to Japan has resulted in closure of 28 out of China's 29 medical schools. Simultaneously, the blockade shut off from that country the supplies of drugs, equipment, and medical literature upon which their physicians had previously depended. At such a time as that it became necessary to create in China a medical service for a large army.

This dilemma has been faced by the Chinese undaunted and with characteristic resource. The following notes on medical education, the Army Medical Service, and medical problems of wartime China were made during an all too brief journey into that country during the summer of 1943.

### Medical Education

Situated in the rice fields near a village outside Chungking is a cluster of temporary buildings, surfaced with mud and painted black. This is the Central Hospital of Nanking and the Shanghai Medical School. Set out in the place of honour between hospital and medical school is the library and reading-room, in which is housed a precious hoard of books and out-dated medical journals that was transported somehow across the whole of China. In the medical school there are 250 students. They live in rooms which accommodate six to eight, furnished with "double-decked" beds, a narrow table, and a single candle for light.

On entering one of the hospital wards I saw on the dirt floor a brazier of burning coals, and on it, boiling in a metal dish, familiar-looking surgical instruments—sterilization which was efficient if unorthodox. This was the obstetrical service of Prof. Gordon King (himself a refugee from Hong Kong).

The patients lay quietly, their beds crowded in neat rows. A young Chinese woman, graduate of Johns Hopkins, was speaking in a low voice, and around her clustered a dozen students. I picked up a case history. It was written in English on flimsy brown paper, detailed, and well organized; temperature chart, progress notes, nurses' notes, all as they should be. Within the ward was the quiet bedside discussion, the atmosphere which should be found in a good teaching hospital anywhere—Baltimore, London, Moscow.

Outside, ducks were quacking and splashing in the rice fields, and along the raised path two coolies approached at a trot, carrying between them a patient in a chair. Along the dirt highroad beyond came the Chungking bus, and, as it stopped, the billowing black smoke of its exhaust betrayed the fact that it burned alcohol—a fuel easily produced in this country of farmers. Passengers alighted and streamed along the path to the hospital.

There are other universities and medical schools that have re-established themselves with similar equanimity, with the same air of undisturbed scholarship in the face of the greatest hardships and personal privations. Many of the schools have, of course, disappeared. Only one in the whole of China continues in its own buildings—the West China Union University Medical School in Chengtu.

Chengtu, in the heart of the Szechwan province, which was formerly the most inaccessible region of China, has become the principal haven of university refuge. Here West China Union University has welcomed on its capacious "campus" National Central (Nanking), Cheeloo (Tsinan), and Peking Union Medical Schools. (After four years the medical school at Nanking moved into separate buildings in Chengtu.) Laboratories, libraries, and class-rooms are shared, teaching and research are carried on, and degrees are granted by each institution separately.

The standard of these medical schools is high. The course in medicine at West China and at Cheeloo is seven years (Peking Union, eight years). The course is divided into two years of premedical work, four of medicine, and one spent

in a rotating internship with field work in public health, followed by preparation of a thesis. Before entering the above medical courses students must have spent six years in primary school and six years in secondary or middle school.

The school of dentistry at West China Union is partly amalgamated with medicine, and the courses are identical in the first four years. The dental course there is also of seven years' duration. They graduate only about 12 men annually, and this was the sole dental school in China until the Nanking National Central University began theirs recently.

It would be impossible for me to follow the fate of all of China's 29 medical schools. There are two refugee institutions in Chungking, working under indifferent circumstances. One of them, Kingsu, is a German-speaking school. North-Western is at Hangchow, in Shensi province, and Hsiangya (Yale in China) is at Kweiwang. There are two medical school "war babies" which have been formed in war years—one at Kweilin and the other at Kweiwang. (For much of this information I must thank Dr. Leslie Kilborn, formerly of Toronto, Dean of Medicine in West China Union University.)

In order to make up for the shortage of medical men to some extent the Ministry of War has created Army Medical Colleges. The largest of these, now at Anshun, was founded 40 years ago. The course lasts only four years instead of the six or seven demanded by civilian Chinese medical schools. About 1,000 surgeons and 400 pharmacists have been graduated in these military colleges.

The effort to keep alight the flame of medical education is gallant enough, but at the present time even Chengtu, with its three medical schools, is qualifying only 50 to 60 graduates yearly. In the whole of Free China Dr. Kilborn estimated that, exclusive of the military colleges, not more than 100 to 150 doctors can be qualified by the universities each year at the present rate. The population of China is said to be between 450 and 600 millions, and the Chinese Government has estimated that the country needs at least 225,000 physicians.

The English-speaking missionary has done splendid work, and is still doing what he can with worn-out instruments and failing drugs. Without considering religion in these pages, his major contribution has been to teach some of the future teachers of Chinese medicine. He has, of course, also introduced the English language, and has presented Western culture in a favourable light, perhaps considerably more favourable than it deserves.

In Chengtu and Chungking the teaching by medical missionaries is on a high academic level. The sabbatical system of returning each to his own country every seven years has given opportunity for postgraduate training, and this, together with the stimulating effect of the obvious need, has made excellent teachers of men who may not have been chosen primarily on the basis of academic distinction.

### The Chinese Army Medical Corps

The number of doctors required, according to Western standards, for the Medical Corps of the Chinese Army would be double the total number of medical men that have been trained so far in that country during its entire history. It is obviously impossible, therefore, to provide an Army, estimated at nine million men, with a medical service that is entirely satisfactory; just as impossible as it is to provide at this time the hundreds of millions of Chinese civilians with adequate medical care.

Nevertheless, the Surgeon-General\* has managed to develop an Army Medical Service. It consists of a few well-trained surgeons, placed at strategic points, and many partly trained officers. Most of his well-trained men are employed to teach first-aid assistants and to supplement the training of others. Thus medical officers have been marshalled in one way and another, and however inadequate the supply might seem, those

\* Lieut.-Gen. Lu Chih Chieh (anglicized to Dick Lu) is well trained, well informed, and resourceful. His headquarters are about ten miles outside Chungking. Here he has direct communication by telephone with each of the nine regular war areas of the Chinese Army. General Dick Lu is a graduate of Peking Union Medical College. After graduation he spent eight years working in the field of physiology. In 1935 he made a study of military medical establishments in America and Europe, spending six months of his time in England. He was recalled at the outbreak of war, and was made Surgeon-General in 1939.

in charge† of the British and American Medical Services during the Burma Campaign report that the performance of the medical corps in the Chinese Fifth Army at that time was remarkably effective under the most difficult conditions.

In another field the Army Medical Service has taken energetic steps to make up, so far as is possible, for the almost complete cessation of supplies from abroad:

A factory for instruments and hospital equipment has been built near Chungking. Here are turned out well-finished surgical instruments, stethoscopes, sterilizers, etc. Near by is an artificial-limb factory running to capacity. The prostheses, made expertly of leather and wood, seemed quite satisfactory. Amputations have been numerous, and 4,500 of the cripples have so far been fitted with artificial limbs, of which 80% have been made in the new limb factory. A still larger number of amputees continue to wait for their limbs.

Also in this vicinity is a herbarium of 200 acres, and there is a similar herbarium with larger acreage in another district. Thus the Army Medical Service is producing *digitalis folia*—said to be more than sufficient to supply the Army—pyrethrum (an insect repellent), *cannabis indica*, *stramonium*, *cascara*, *rhubarb*, and a few other drugs. They are producing *Saxifrageaceae* from which may be extracted a glucoside reputed to have an antipyretic and antimalarial action. Many drugs, of course, such as the sulphonamides, cannot yet be manufactured.

#### Problems of Military Medicine

At the present time, instead of war casualties being the primary consideration of the Army Medical Service, they take third place, after malnutrition and infectious disease.

Malnutrition comes first. This is not due so much to deficiency in calories, for the supply of partly polished rice is often adequate. It is due to deficiency in the protein, fat, and vitamins available to the Army. Vegetables are raised in some parts of China; meat is available in others. The difficulty of distribution arises from lack of transport facilities. Nevertheless, when this problem was discussed with Generalissimo Chiang Kai-shek he stated that the soldiers generally receive meat twice a week—a claim which can hardly be made for the population as a whole.

Next in importance after nutrition is the problem of infectious disease, and here the acute shortage of specific drugs is noteworthy. Malaria, of course, is prevalent in some areas, and they seem to have little quinine and less atabrin. Dysentery is frequent, and the supply of sulphaguanidine has been insufficient for adequate trial, although sulphanilamide is said to have been helpful. Typhus has had a relatively low incidence except at times in North China. Typhoid and relapsing fever have often presented serious problems, as have scabies, leg ulcers, and trachoma. During a period of 4½ years a total of 967,660 cases of sickness were analysed by the Surgeon-General from various units of the Army Medical Service Administration; 29% of these patients were suffering from infectious diseases, 13.6% from respiratory diseases, 20% from gastro-intestinal disease, and 17.6% from diseases of the skin.

Battle casualties were most numerous early in the war, and will be again, no doubt, when increased communication brings in supplies and enables the Chinese Army to take up offensive warfare. In 1937 the ratio of wounded to sick was 2 to 1 in the Army; in 1942 it was 1 to 4. Of nearly a million casualties subjected to analysis, 6.1% were suffering from injury to the head, 6.5% to chest, 6.6% to abdomen, 78% to extremities, and 2.5% to other areas.

Evacuation of wounded has always been difficult. It is carried out chiefly by man-power. Carriers can do 30 kilometres in a day, but the casualty-collecting points may be 20 to 50 kilometres behind the scene of action, and evacuation hospitals 100 kilometres. Consequently, many wounded perish without surgical treatment or are cared for and nursed back to health in farmhouses of the district. Blood-donor clinics do not exist, and blood derivatives for the treatment of shock are not available.

#### Auxiliary Medical Units

Very important aid is given to the Army Medical Service by Auxiliary Army Medical Units of various types. The surgeons in these units are better paid than the Regular Army medical

officers. They are moved about and placed at strategic points where the fighting is most active. Such units have been provided from the following sources: (1) the Chinese Red Cross, which has supplied by far the largest number; (2) the New Life Movement; (3) National Health Administration anti-epidemic teams; (4) E.M.S.T.S. units (emergency medical training schools, which have been set up at eight different points near the war areas, train medical aides and provide special courses for medical officers); (5) Friends Ambulance units; (6) British Red Cross unit. In addition to this, the mission hospitals, if near the battle area, have helped greatly and have played a most important part in the care of casualties from Japanese bombing raids.

#### The General Situation

Aside from military establishments, there are in Free China to-day about 15,000 hospital beds available to the public. These beds are made up roughly as follows (figures from Dr. A. Stewart Allen, formerly of Montreal, now of Chungking):

(1) National Health Administration (Chinese Government)	5,000
(2) Private Chinese hospitals (chiefly attached to medical schools or colleges supported to some extent by the Chinese Red Cross)	2,500
(3) Mission hospitals	7,500
Total	15,000

The mission hospitals receive their major support from the Chinese patients, who are admitted in categories of charity, semi-private, and private. The foreign staff, including doctors and nurses, receives financial support from abroad. But, in general, foreigners are being steadily replaced by newly trained Chinese.

The National Health Administration (N.H.A.)† concerns itself with the problems of public health, the control of epidemic disease, and the distribution of essential drugs. It has established county health centres, which serve a very useful purpose. However, this department is not charged with the care and rehabilitation of wounded soldiers, as in the case of its counterpart in Allied countries.

The Chinese have always taken pride in a high tradition of scholarship. It is therefore not surprising to discover that a considerable amount of medical research is being conducted under the adverse circumstances of wartime. Dr. Joseph Needham, British Scientific Mission, has surveyed the present situation in China in regard to scientific research. (*Nature*, 1943, 152, 9, 26, 64, 343, 372.)

#### Conclusion

Drugs, instruments, and, most of all, medical literature are badly needed now by physicians, medical teachers, and Army surgeons in China. But what the country seems to need more than anything else is medical men—not foreign physicians who cannot speak the language, but Chinese, trained in medicine at home or abroad—200,000 of them!

The problems faced so resolutely now by the Surgeon-General of the Chinese Army are similar to the problems faced by the National Health Administration to-day and to be met in the days to come. These problems will be of paramount importance in the period of post-war rehabilitation. Education is the field which presents the greatest opportunity for assistance. In this field, medicine should be given high priority to help China win her battle and establish herself securely as a great and independent nation.

† For a description of the work of this department and the general health problems of China see *China's Health Problems*, by Szeming Sze, Chinese Medical Association, Washington, D.C. (reviewed in *British Medical Journal*, Nov. 6, 1943).

R. E. Burger and C. B. Morton (*Surgery*, 1944, 15, 313) review the literature and record five cases of infection by *Torula*. In the first, one of torulosis of the central nervous system, the diagnosis was made at necropsy. In the second, a case of generalized torulosis, a diagnosis of Hodgkin's disease was made from biopsy material. In the third, a case of localized torulosis of the thigh, an apparent cure was effected by radical surgery and potassium iodide internally. In the fourth, a case of torulosis of the C.N.S., the diagnosis was made by smear and culture of spinal fluid. In the fifth, death was due to cerebrospinal torulosis.

† Major-Gen. Thompson, D.D.M.S., Bengal, and Col. Williams, Chief Surgeon to the American Forces in the China-Burma-India Theatre.

## BIRTHDAY MEDICAL HONOURS

The names of the following members of the medical profession were included in a Birthday Honours List published in Supplements to the London Gazette on June 8:

*Order of Merit*

Sir HENRY HALLETT DALE, G.B.E., M.D., D.Sc., LL.D., F.R.C.P., President of the Royal Society.

*K.B.E. (Military Division)*

WILLIAM TYRRELL, C.B.E., D.S.O., M.C., M.B., B.Ch., A. Vice-Marshal R.A.F.

*Knighthood*

ERNEST ROCK CARLING, M.B., F.R.C.S., Consultant Adviser in Surgery and Adviser on Casualty Services to the Ministries of Health and Home Security.

WILLIAM ALLEN DALEY, M.D., F.R.C.P., Medical Officer of Health and School Medical Officer, London County Council.

ALEXANDER FLEMING, M.B., F.R.S., F.R.C.P., F.R.C.S., Professor of Bacteriology, University of London. Discoverer of penicillin.

HOWARD WALTER FLOREY, M.B., Ph.D., F.R.S., Professor of Pathology, University of Oxford. For services in the development of penicillin.

ALFRED CHAD TURNER WOODWARD, M.B., Ch.B., F.R.C.S., Chairman of the Worcestershire County Council.

*C.B. (Military Division)*

GILBERT ALAN BLAKE, M.B., K.H.S., Major-Gen., late R.A.M.C. STANFORD CADE, F.R.C.S., M.R.C.P., Acting Air Cmdr. R.A.F.

PHILIP HENRY MITCHELL, C.B.E., T.D., M.D., M.S., F.R.C.S., K.H.S., Col. (Temp. Major-Gen.), late R.A.M.C., T.A.

GORDON WILSON, C.B.E., M.C., M.B., K.H.S., Major-Gen. (local Lieut.-Gen.), late R.A.M.C.

*C.I.E.*

HERBERT EDWARD MURRAY, M.D., M.Ch., Lieut.-Col. I.M.S., Professor of Midwifery, Medical College, and Superintendent Medical College Hospitals, Calcutta.

*C.B.E. (Military Division)*

EDWARD BRUCE ALLNUTT, M.C., M.R.C.S., Col., late R.A.M.C. GRANT MASSIE, M.S., F.R.C.S., Lieut.-Col. (Temp. Col. local Brig.) R.A.M.C.

CHARLES JAMES SIDNEY O'MALLEY, M.B., B.S., Acting Group Capt. R.A.F.

RICHARD ALUN ROWLANDS, O.B.E., M.D., Temp. Surg. Rear-Admiral.

JOHN MURRAY WEDDELL, F.R.C.S., Col. (local Brig.) late R.A.M.C.

*C.B.E. (Civil Division)*

RICHARD CHARLES ALEXANDER, M.B., F.R.C.S., Ed. Surgical Director, Emergency Medical Service, Eastern Region of Scotland. Professor of Surgery, University of St. Andrews.

JOHN BLACK GRANT, M.D., D.P.H., Director, All-India Institute of Hygiene and Public Health, Calcutta.

ARCHIBALD HECTOR MCINDOE, M.Sc., M.S., F.R.C.S., Civilian Consultant to the R.A.F. in Plastic Surgery.

JOHN PHIMISTER MITCHELL, O.B.E., M.D., Colonial Medical Service, Medical Superintendent and Principal, Medical School, Mulago, Uganda.

WALTER PERCIVAL YETTS, O.B.E., D.Lit., M.R.C.S., Professor of Chinese Art and Archaeology, London University.

*O.B.E. (Military Division)*

MONAWAR KHAN AFRIDI, M.D., Major (Temp. Lieut.-Col.) I.M.S. VINCENT HENRY LUDOVICI ANTHOISZ, Lieut.-Col. Ceylon Medical Corps.

HAROLD JOHN BENSTED, M.C., M.R.C.S., Lieut.-Col. R.A.M.C.

WILLIAM DALE, M.R.C.S., Major (Temp. Lieut.-Col.) R.A.M.C.

CHRISTOPHER ROBSON DUDGEON, M.C., Major (Temp. Lieut.-Col.) R.A.M.C.

JOHN GERRARD HOLMES, M.D., Surg. Cmdr. R.N.

GEORGE MACKIE, M.D., Lieut.-Col. (Acting Col.) Worcestershire Home Guard.

GEORGE HENRY MORLEY, F.R.C.S., Wing Cmdr. R.A.F.

JAMES WALLS ROSS, E.D., Lieut.-Col. R.C.A.M.C.

HENRY ROBERTSON RUTTEN, M.D., Acting Temp. Surg. Cmdr.

R.C.N.V.R.

*O.B.E. (Civil Division)*

ALEXANDER MACANDREW GILLESPIE, M.B., F.R.C.P., Ed. Colonial Medical Service, Senior Specialist, Gold Coast.

Mrs. HELEN MARY TWINING, M.R.C.S., D.P.H., For medical services in Mauritius.

BERTRAM OSBORNE WILKIN, M.B., Ch.B., Colonial Medical Service, Medical Officer (Health), Tanganyika Territory.

*M.B.E. (Military Division)*

JOHN AMOS, M.B., Capt. (Temp. Major) R.A.M.C.

LINDSAY BARCLAY, Capt. (Temp. Major) R.A.M.C.

SAMUEL JOHN CHESLER, Major R.A.M.C.

ALDINGTON GEORGE CURPHEY, M.C., Major Jamaica Medical Corps.

MUHAMMAD ABDUL AZIZ KHAN GOHANAVI, Subadar I.A.M.C., Indian Army.

JAMES GEORGE KEEPER LINDSAY, Major R.C.A.M.C.  
MICHAEL WHITTAKER CARLTON OLDFIELD, M.B., F.R.C.S., Capt. (Temp. Major) R.A.M.C., T.A.  
JACK PENN, Temp. Major S.A.M.C.  
ELAINE MARGARET CATHERINE SALMOND, M.D., F.R.C.S., Capt. (Temp. Major) R.A.M.C.  
ATMA SINGH, Subadar I.A.M.C.

*M.B.E. (Civil Division)*

RAI BAHADUR SANTOSH KUMAR MUKERJI, M.B., M.R.C.P., Lecturer in Medicine, King Edward Medical School, Indore, Central India.

ABU ASHRAF MOHAMMAD WAJIB, M.R.C.S., Chief Medical Officer, Emergency Hospitals and Medical Supplies, Bengal.

*B.E.M. (Civil Division)*

SAVENACA VEIKOSO, Native Medical Practitioner, Fiji.

The honour of knighthood is to be conferred also on PERCIVAL HARTLEY, C.B.E., D.Sc., F.R.S., Director of Biological Standards, National Institute for Medical Research.

We print below the conclusion of the Birthday medical Honours List, published in a Supplement to the London Gazette on June 10:

*O.B.E. (Civil Division)*

NIGEL CORBET FLETCHER, M.B., B.Ch., Surgeon-in-Chief, St. John Ambulance Brigade.

ROY DYSON LANGDALE KELHAM, M.R.C.S., L.R.C.P., Principal Medical Officer, Ministry of Pensions.

JOHN ERNEST NICOLE, L.M.S.S.A., D.P.M., Medical Superintendent, Winwick Emergency Hospital, Warrington.

*M.B.E. (Civil Division)*

WILLIAM BLACKWOOD, D.S.O., M.B., Ch.B., Lieut.-Col. County Commissioner, St. John Ambulance Brigade, Cornwall.

HELEN STANORING, M.D., D.P.H., Senior Assistant Medical Officer of Health at Hull for Maternity and Child Welfare. For services to Civil Defence.

OSKAR TEICHMAN, D.S.O., M.C., T.D., M.R.C.S., L.R.C.P., Major. Local Army Welfare Officer, Southern Command.

## A NATIONAL MATERNITY SERVICE

A report on a National Maternity Service has been prepared on behalf of the Council of the Royal College of Obstetricians and Gynaecologists by the Maternity and Infant Health Services Committee under the chairmanship of the President, Mr. Eardley Holland. It is published this week by the College (58, Queen Anne Street, London, W.1) as a pamphlet, price 1s. 6d. Comment must be deferred to a later issue, but we print now the committee's summary and conclusions.

The practice of obstetrics (midwifery) must be considered on a broad national basis, in the light of the ideas and needs of to-day.

In the *Introductory Section* the present position has been described. It has been pointed out that the maternal mortality rate is still too high despite the fact that there has been a considerable fall in the last few years. We believe that the fall has been due not so much to improvement in the technical side of obstetric practice as to the application of new methods and drugs in the treatment of shock, haemorrhage, and sepsis, and to modern technique in the investigation and prevention of bacterial infection. We believe, also, that the fall has been helped by the increase in institutional midwifery, and the better planning of their maternity services by a number of local authorities. The stillbirth rate started to fall soon after the war began; the fall is slight and the reason for it is not yet clear. The neonatal mortality rate has been falling slowly for some years but is still too high. It is known that in some geographical areas and in some boroughs these obstetric mortality rates are much lower than the average, and in others the rates are much higher. There can be no reasonable doubt that the general application of the lessons learnt from a study of conditions existing where the rates are low would result in a considerable fall in all three and a rise in the general level of maternal and infant health.

In the *Social and Economic Section* we have stated the evidence that poverty—with its accompanying deficient nutrition, bad housing, and overcrowding—contributes greatly to stillbirth and neonatal mortality, and is not without effect on maternal mortality and morbidity. Moreover, it is very necessary to remember that when poverty and its accompaniments exist the technical services cannot function effectively.

Under the *Technical Services Section* we emphasize that in establishing the quality and maintaining the standard of a maternity and infant health service the technical side is dominant. The quality of the technical side depends first of all on the quality of the personnel—obstetric specialists, general practitioners, and midwives—as well as on their number, availability, and distribution.

We propose that the country be divided into maternity areas of a size capable of giving a complete service, and suggest areas yielding about 15,000 births a year as of suitable size for the purpose. We propose further that there should be large health regions based wherever possible on a university medical school, the maternity areas mentioned above becoming constituent areas of the large regions. In a region the service would be based on a key or primary centre, consisting of not fewer than 100 lying-in beds, with at least a third of that number of ante-natal beds, ante-natal and other clinics, a department for infants under a paediatrician, laboratories, teaching and research facilities. A key centre should, whenever possible, be part of a university medical school, and at the head would be an obstetrician of professorial status, whole-time and resident in the centre or nearby. The key centre would set the standard and supply the leadership and inspiration of the whole region. In an area the service would be based on divisional maternity centres, closely associated with the key centre, and at the periphery would be small local centres.

The whole service, in region and areas, should act as a single unit, with all parts integrated—maternity centres, ante-natal and other clinics, obstetricians, paediatricians, general practitioners, midwives, health visitors, home helps, laboratory services. We regard this principle of integration as absolutely essential for efficiency. The service, therefore, should be under a single administrative authority. We believe that the qualification for general practitioners to work in a National Maternity Service should be special and approved post-graduate experience.

One of the difficulties, to begin with, of working the sort of service we suggest is the shortage of well-trained personnel and their uneven distribution throughout the country. In London and most large towns there are enough obstetric specialists; in other areas and towns there are too few, and in still others there are none. Training centres must come before additional personnel can be trained. The university key centres would be the undergraduate schools; some of the divisional centres would be postgraduate schools and schools for midwives. The whole process would have to be gradually evolved until the standard of practice had been considerably raised, and could be undertaken by a select corps of men and women based on high-class maternity centres. We have no doubt that the wider application of knowledge, more and better personnel and institutions, and more efficient planning would greatly lessen the wastage of maternal and infant life and health, and would increase the health, happiness, and vitality of the nation.

us in which an infected eczematous area was treated by crude penicillin in a lanette wax and water base (containing 1 petroleum jelly) and was irritated by this preparation.—We are,

### Sensitivity to Liver Extract

SIR,—I read with interest the article by Drs. McSorley and Davidson on sensitivity to liver extract (May 27, p. 714). My experience has in most respects been similar to theirs: nearly all the severe cases I have seen have been secondary—i.e., have occurred in patients who had been having liver injections for months or years. Twice they have occurred when the patient had to change the preparation used owing to her usual brand being in short supply. Once the allergic state is established the patient may be found sensitive to every preparation available or only to one or two.

I think, however, it would be a mistake to assume that most severe cases can be desensitized by the rush method employed by Drs. McSorley and Davidson. I have several times tried a method similar to theirs without success, to find later that the same patient was quite easily desensitized by injections given at daily intervals. The method I now employ is to put severe cases on a hog-stomach preparation while desensitization is being carried out, test the skin response to various dilutions of the liver extract to be used, and start with a dose well below that which causes a positive skin reaction. Unsuccessful attempts to desensitize may lead to a marked degree of hypersensitiveness. In such a case I have seen a well-marked allergic reaction to a dose of 1 minim of 1 in 100 solution of anahamin. The patient in whom that reaction occurred was, however, successfully desensitized over a period of two months, during which time he had a hog-stomach preparation daily and several blood transfusions.

Nearly all the patients I have seen exhibit severe reactions have been found on inquiry to have had minor symptoms following the previous injection. I think nearly all these severe reactions would be avoided if: (1) all patients at the beginning of liver therapy were instructed to report any unusual symptom noted to follow an injection—e.g., skin rashes or flushing, feeling of tightness in the chest, headache, vomiting; (2) any doctor changing a patient from one liver preparation to another gave a test dose of 0.05 c.cm. of the substitute preparation and waited 20 minutes before giving the full dose.—I am, etc.,

C. T. ANDREWS.

## Correspondence

### Penicillin for Skin Diseases

SIR,—We should like to reply to a few points raised by Majors Taylor and Hughes, whose letter we were interested to read in the *B.M.J.* of May 20 (p. 699).

When we started to use the spray technique in Nov., 1943, we felt that a quicker cure was one of the advantages it might offer, and that, if this was so, it would be facilitated by the use of a relatively strong solution. It was for this reason that we used a strength of 1,000 units per c.cm. We would not claim that this concentration is necessarily the best one for future use. Development, during treatment, of complete resistance to penicillin was not observed in any of our cases. In Cases 7 and 8 of our sycosis series there was, as stated (*B.M.J.*, April 15, p. 524), a lessening of sensitivity, but even so Case 7 recovered temporarily after further treatment. In Case 4 of the blepharitis series, although no sensitivity test was performed *in vitro* immediately before the use of the ointment was stopped, the condition cleared up rapidly when solution alone was applied to the lids. There is therefore no evidence to suggest that penicillin-resistant organisms were responsible for the deterioration of these cases, and indeed from the clinical point of view it was obvious that they, and Cases 5 and 10 of the sycosis series, were suffering from a chemical irritation of the skin, as distinct from an aggravation of the infective process.

The cases we described provide no direct evidence incriminating the petroleum jelly as the cause of irritation. Cases 5 and 10 of the sycosis series and Case 4 of the blepharitis series were eventually irritated by the penicillin ointment. The bad effect produced by the solution alone in Case 8 of the sycosis series tends to colour the view that it was some impurity in the penicillin rather than the petroleum jelly which caused the irritation. This is supported by a recent experience of one of

### Nutritional Oedema in a Vegetarian

SIR,—It does not seem necessary to ascribe the oedema in the case described by Dr. Holmes (May 6, p. 620) to myocardial weakness. The plasma proteins were well below the level at which oedema might be expected. This reduction of plasma proteins during the treatment of anaemia is due to the synthesis of haemoglobin at the expense of other body proteins (see Heath and Taylor, *J. clin. Invest.*, 1936, 15, 411).—I am, etc.,

London Hospital.

J. R. MARRACK.

### Ketosis in Children

SIR,—To obviate any further misconstruction of my remarks on this subject (*Journal*, April 8, p. 503) I would reply to the points raised by Dr. A. Cruikshank (April 29, p. 602) as follows:

(a) I did not say that these children were allergic to fats but that the commonest foods to which children are allergic are rather than the fat—as, for example, an urticaria to cod-liver oil usually occurs in a fish-sensitive child.

(b) Dr. Cruikshank has never experienced the occurrence of acidosis (or does he mean "ketosis"?) as soon as bacon fat or milk is added to the diet. The first case mentioned in Dr. Evans's original paper (*Journal*, March 25, p. 432) is one where such attacks were induced by the smallest quantity of milk, even after the fat had been removed.

(c) The relief obtained by injecting adrenaline in these cases bears no analogy to its effect in relieving hypoglycaemia due to an overdose of insulin, because when insulin is given it is probable that there is a big supply of glycogen present in the liver which only requires quick release and conversion into blood sugar. But the essence of these ketosis attacks is that they occur when the body's sugar and glycogen supplies have been depleted following emotion, exertion, or excitement, so that there is probably not much glycogen left to be converted into blood sugar by the adrenaline.

(d) The administration of alkalis in these cases has no biochemical foundation, as in general there is no "acidosis" in the true sense of the word, no acid change in the H-ion concentration of the blood, so there is nothing to be neutralized.

(e) Most of these ketosis attacks last only a few days irrespective of the treatment to a large extent, so Betty's response to the diet and administration of alkalis may have been coincidental and not necessarily the immediate result of the treatment. Let our treatment be prophylactic by finding out to what Betty is sensitive, and, if a food, give her an acid to help her digestion, and thus prevent further ketosis attacks during childhood and possibly migraine in later life, and so make her a different and better child and not "her sweet little self again"—that is, liable to further attacks.—I am, etc.,

London, W.1.

GEORGE BAY

### Symptomless Enlargement of the Oesophagus

SIR.—Dr. J. L. D'SILVA's case (June 3, p. 750) may apparently be classed with those of the rare "sigmoid" and "corkscrew" types of megaoesophagus discovered at necropsies after fall from height or other accidents or at x-ray examinations of the thorax made for various reasons, but not on account of any suspected oesophageal disease. The deformity seems to be developmental—that is to say, potentially, if not to some degree actually present at birth. But this view does not get us much further as to the causation. Predisposition does not imply the absence of causative factors, for veins of the lower extremities are often "predisposed" to become varicose, though no one would claim the absence of direct causative factors in such cases. Abnormal conditions of Auerbach's plexus may not be the only cause of megaoesophagus. There may even be some unknown general agent at work which in certain individuals acts selectively (i.e., with the effect of a general agent on local predispositions) on the oesophagus—just as in rare cases of acromegaly the excess of growth hormone may act selectively on the scalp, causing it to increase both in thickness and in breadth and length, so that in order to keep fitted to the skull it has to become furrowed (*cutis verticis sulcata* of acromegaly). In these cases of megaoesophagus, as has often been observed, the increase in length as well as in breadth causes the oesophagus to become bent or twisted.—I am, etc.,

London, W.1.

F. PARKES WEBER

### Aerial Convection from Smallpox Hospitals

SIR.—I am grateful to Prof. Ralph Picken and Lieut.-Col. P. G. Easton for their letters (May 20, p. 699) giving additional evidence in support of the theory of aerial convection of smallpox infection. Prof. Picken refers to Sir Alexander Macgregor's experience in the Glasgow epidemic of 1920-1. I may say that in the more recent outbreak of 1942 aerial convection from the Glasgow smallpox hospital provided—to those who accept the theory—a simple explanation of the connexion between the "ship's group" of cases and the "city group," otherwise almost inexplicable. Aerial convection also provided a simple explanation of the remarkable outburst in Leicester in 1903, when in the space of eleven days (after a lull of a fortnight without cases) 65 cases occurred in 61 houses in 58 streets scattered over two-thirds of the city (the district which escaped was the furthest from the smallpox hospital), and in 62 of the 65 cases not the slightest clue to the source of infection (apart from aerial convection) could be discovered. The 37 adults who went to work were employed in 32 different work-places, and 14 children attended 11 different schools. Obviously the "missed cases" theory is quite inadequate to explain such an outburst. As I said in my report on the outbreak, the infection appeared to have "dropped from the clouds." Since I have learnt from

my recent study of the subject how very strong the evidence in support of the theory is, I venture to say that is just where it did come from.

Now that we are learning the limitations of the protection conferred by infant vaccination, it is all the more necessary that every aspect of the problem of how smallpox is spread should be carefully studied. I hope, therefore, that those who may have thought that the theory of aerial convection had been exploded will reconsider the question.—I am, etc.,

Leicester.

C. KILLICK MILLARD.

### Strangulated Femoral Hernia

SIR.—The memorandum by Mr. D. K. Mulvaney (June 3, p. 751) affords an opportunity to refer briefly to two points in the operation. In the early case, if, after opening the sac, difficulty in reduction is encountered, the abdomen should be opened above the inguinal ligament, to expose and control the limbs of the loop. They are gently held by one hand. The bowel in the sac is held by the other. One has command now of the whole situation, because, by very gentle, sliding, to-and-fro movements of the hands, working together, the loop is safely delivered into the abdomen. This measure usually obviates any need to divide the constriction ring.

If, on opening the sac in the latter case, the bowel is non-viable and the decision made to perform a resection and anastomosis, how may this be safely performed and infection of the peritoneal cavity prevented? The infected contents of the sac are swabbed out. The herniated loop is delivered further and resected between clamps. The ends of the bowel are then closed with purse-string sutures, the clamps removed, and the ends of the sutures left long. The area is given a final toilet with saline or weak creosol lotion. The surgeon changes his gown and gloves and opens the abdomen above the inguinal ligament. The purse-string sutures are threaded up through the femoral ring, and thus the ends of the bowel are brought into the abdomen, delivered and anastomosed. These measures may be well known to some, but others will find them useful if they encounter this emergency.—I am, etc.,

Edinburgh

W. A. COCHRANE.

### Administration of Pentothal

SIR.—Dr. Montuschi (May 27, p. 731) has pointed out that many thousand intravenous anaesthetics will have to be administered in the next few months by relatively unskilled anaesthetists. For some time I have realized this and have endeavoured in teaching students at the Middlesex Hospital to give some fundamental rules, rather more comprehensive than Dr. Montuschi's excellent suggested admonition to limit the dose. I have recently published a synopsis of my undergraduate teaching on intravenous anaesthesia in the *Middlesex Hospital Journal*, March, 1944. If I may recapitulate the main points in your *Journal*, they may be of help to many temporary anaesthetists.

#### Technique of Injection

1. Never use a stronger solution of pentothal than 5%—i.e. 1/2 g. in 10 c.cm.
2. Use a 10-c.cm. capacity eccentric nozzle syringe. This size is handier to hold than a 20-c.cm. and by its size will limit any injection to 1/2 g. The eccentric nozzle makes venepuncture easier.
3. Use sharp, short-bevel needles.
4. Have your patient in a stable position, so that when he relaxes he will not slump into a new position.
5. Be stable and comfortable yourself; sit, stand, or kneel at your convenience; do not balance on one leg and support the patient's arm on the other knee, and do not bend down over a very low bed.
6. Test the intravenous position of your needle point by aspirating blood back before you inject.
7. Inject slowly, watching: (a) the patient for developing unconsciousness and continued respiration; (b) the needle point to be sure you are still in the vein; (c) the syringe to see how much you are giving.
8. Lastly, but most important, keep the airway clear.

#### Dosage

There is no fixed dose. The amount that each patient needs can be determined only at operation by his reaction to the drug as it is administered. While the first few c.cm. are administered slowly the patient should be watched, his reaction to simple questions noted until he is seen to be asleep. He has now had the sleep dose. He

will need for induction or any very short anaesthesia a total of at least twice the sleep dose. The initial injection should never exceed a total of three times the sleep dose. More pentothal may be necessary during the operation; each such subsequent injection should not exceed the sleep dose.

#### Shock

Extra care should be taken in shocked patients to determine the correct dose, which is always much smaller than in normal patients. Hattord (*Anesthesiology*, Jan., 1943) reports several fatal injections of 0.5 g. in shocked Pearl Harbour casualties, and I am not surprised. This shows that Dr. Montuschi's injunction is not enough. On the other hand, in the same volume of *Anesthesiology* Adams and Gray report successful extensive thoraco-abdominal surgery in a shocked woman, using repeated very small doses.—I am, etc.,

London, W.1.

F. W. ROBERTS.

SIR,—In his letter (May 27, p. 731) Dr. Montuschi gives advice to the occasional anaesthetist, should he wish to give pentothal during the coming months. This presumably refers to expected casualties when the great offensive is launched, and in that case I know that I shall not be alone in disagreeing with some of his suggestions.

In my opinion there are two definite scales of dosage of pentothal. One is for normal fit people, aged approximately from 18 to 40. The other is for everybody else, especially the anaemic, the debilitated, all elderly persons, acute obstructions, and casualties. The greatest risk of overdosage is with cases that have had repeated doses of morphine, or high doses. Bad R.A.F. casualties are good examples of the last-named, as they usually get morphine gr. 1/2 at the time of the accident (a practice with which I do not disagree). The dosage in the second group can be as low as one-tenth of that in the first group, and failure to appreciate this has undoubtedly led to loss of life. This principle should be fully explained to all students, who should have as great a respect for pentothal as I think they have for a spinal anaesthetic. Dr. Montuschi only refers to the first group, and as such his advice is sound. In these cases there is a considerable margin of safety, and if the occasional anaesthetist gives pentothal to these cases only he should get most satisfactory results; but to give "the whole of the small ampoule fairly rapidly" to the second group is sure to add to the already unnecessarily long list of pentothal deaths. I am sure that two people could be killed with that "small ampoule," providing they were bad risks.

It has been my lot to have to anaesthetize many serious casualties of all types, many of these being R.A.F. personnel. The only anaesthetic that I now give is (except for abdominal work, when I add a thoracic block) continuous pentothal, gas, and oxygen; but I am very convinced that one has to approach these cases very carefully. The keynote to safety is much oxygen and little pentothal. The worse the case the more certain I am that oxygen must be given before the pentothal, and that nitrous oxide should be introduced very slowly. The pentothal should be a 2½% solution and not the usual 5%; the rate of flow should be very slow. During the first five minutes it is wise not to give more than 1 c.cm. at a time. I have seen several cases lose consciousness on 1 c.cm. of the 2½% solution—i.e., 0.025 g. It would therefore not be surprising if such a case died after 3 to 4 c.cm. of a 5% solution given fairly quickly.

Let there be no hurry to reach deep anaesthesia. Many cases have yet to be undressed, etc., and for this very light anaesthesia is satisfactory. Nitrous oxide can be added if the colour remains good, but if it is less than good this should not be done. When adding N<sub>2</sub>O I start with a 50% mixture, and never go below 20% oxygen on a bad case. More pentothal is much safer.

I also feel strongly that no one should use pentothal unless he can perform the simple procedure of inflating the lungs with oxygen by pressure on the bag. Then, if at any time respiratory depression should follow the administration of pentothal, the patient can be kept a perfect colour in absolute safety until respiratory movements recommence. This is so easily done that the surgeon is unlikely to know that the patient has stopped breathing. I have no doubt that if this was more widely known and practised the intravenous barbiturates would have a cleaner record.

Finally, even in these days of wholesale spending, economy should matter, and as a large ampoule is almost the same price

as a small one, I see no reason why the anaesthetist should be advised "to forget the large one." What is left over from one case in a list can be used for the next case.—I am, etc.,

H. B. C. SANDIFORD,  
E.M.S. Anaesthetist, Region 12.

#### Post-anaesthetic Vomiting

SIR,—In an article recording painstaking research on the effect of nicotinic acid on post-operative vomiting (May 27, p. 719) the authors state that results were "not significant." This leads me to think that perhaps it is not generally known that post-operative or, as it should be termed, post-anaesthetic vomiting can be controlled in almost all cases by the oral administration of 5 to 20 minims of a solution of adrenaline chloride 1 in 1,000 in an ounce or so of water. A single dose is often sufficient, but it may be repeated with safety if required.—I am, etc.,

Leamington Spa.

BARBARA G. R. CRAWFORD.

#### Ether and the Oxford Vaporizer

SIR,—The article by Drs. Mushin and Wood on the effect of nicotinic acid on post-operative vomiting (May 27, p. 719) interested me as an example of the very valuable and original work that is constantly being carried out by the Nuffield Department of Anaesthetics.

I was, however, also interested in the light that this article inadvertently threw upon the actual incidence of post-operative vomiting after ether under the most favourable conditions. This series of 89 cases, admittedly uncomplicated, were anaesthetized by an expert using the Oxford vaporizer on its "home ground," and the admitted incidence of post-operative vomiting was no less than 74%! Truly "the cat is out of the bag"! The Oxford vaporizer is a very ingenious and excellent apparatus, which, to my mind, has only one disadvantage—namely, the fact that it delivers ether to the patient. Many writers in your columns have rightly eulogized the apparatus, but they have, almost without exception, been so overcome by their enthusiasm as to claim that the patients receiving ether through this medium were to a great extent spared those ill effects which are the inevitable aftermath of this anaesthetic.

The truth, as it is now revealed, confirms my own experience that ether unfortunately still remains ether even after passage through the Oxford vaporizer. It is a pity that the Oxford vaporizer was not designed twenty years ago. To-day the anaesthetist is rarely justified in submitting his patient to the discomforts and dangers attendant upon ether. It is to be hoped that the ingenuity and excellence of design embodied in the Oxford vaporizer will, before long, be put to better practical use.—I am, etc.,

Bournemouth.

S. F. DURRANS.

#### Bone-marrow Transfusion in Children

SIR,—We are particularly interested in the recent article on "Bone-marrow Transfusion in Infants and Children" by Dr. Janet Dr. Gimson (June 3, p. 748). In this hospital a great number of transfusions are given to infants and children of all ages from one day to sixteen years. The average number of such transfusions exceeds forty per month.

Intravenous technique appears to be considered a complicated and difficult procedure, but the resident medical officers here rapidly become extremely proficient and only a few minutes are required to set up a transfusion. It is our opinion that transfusions of all fluids are best given to the infant or child intravenously. Thereby the amount of fluid which actually reaches the circulation can be most intimately and directly controlled in the safest and quickest manner.

Dr. Gimson mentions "the haunting danger" of osteomyelitis. We feel this to be a very real one. Adequate skin preparation for an operation involving bone cannot be done when parenteral fluid is a matter of urgency. Why, therefore, should it be necessary to jeopardize bone when so simple an alternative is at hand?—We are, etc.,

Alder Hey Children's Hospital, Liverpool.

## Death Rate from Peptic Ulcer

SIR.—I read with great interest Sir Henry Tidy's article in the *Journal* of May 20 on the death rate from peptic ulcer in Great Britain, 1912-38. It is a painstaking study which gives much food for thought. Somewhere in it he locked the secret of the aetiology of peptic ulcer. Several factors in the aetiology of peptic ulcer are undoubtedly involved. First, the rising age of the population. In 1937 there were 2,272 deaths from gastric ulcer in males (Registrar-General's Statistical Review, 1937, the last report available to me). The percentage distribution by age was as follows:

0	..	..	0.02%	40	..	7.5%
1	..	..	..	45	..	9.8%
5	..	..	0.4%	50	..	14.7%
10	..	..	..	55	..	14.4%
15	..	..	0.4%	60	..	13.5%
20	..	..	0.8%	65	..	10.7%
25	..	..	2.6%	70	..	7.1%
30	..	..	3.8%	75	..	7.8%
35	..	..	5.8%	80	..	2.2%

Therefore a large percentage of the mortality in males from gastric ulcer occurs at ages 40 to 70, especially 50 to 65. It is thus a disease of later life, and should be classed in its age incidence with cancer, diabetes, myocardial disease, and other degenerative diseases. The rising age of the population should result in increase of the gastric ulcer rate. A falling birth rate and saving of infant lives should show its effects after 30 or 40 years in increased figures for mortality from peptic ulcer. Why, then, the stationary rate 1912-21? There was a war (1914-18); there was the influenza epidemic, affecting males of all ages up to 55; there was dieting. Between the years 1909 and 1934 the intake of calories increased by 6%, but of animal fats by 25% (John Boyd Orr). This increase was interrupted in the war years, and after the war began to play its part.

But the question of the peptic ulcer is only a part of the larger question. The crude death rate per million in 1927 was 12,336, and in 1937 it was 12,419, an increase of 83 per million. But although the difference is comparatively slight, there were big falls in some diseases, balanced by big rises in other diseases.

Tuberculosis—a very steady fall till 1936 in all forms (972 per million to 695 per million); the only exceptions are genito-urinary tuberculosis, constant at about 7 per million; acute disseminated tuberculosis, constant at about 16.

Rheumatic fever	..	40 to 22	Bronchitis	..	849 to 436
Perniciosa anaemia (a steady fall from 1932)	..	68 to 55	Pneumonia	..	943 to 720
Meningitis	..	37 to 22	Inflammation of the stomach	..	35 to 15
Tuberculous	..	20 to 14	Diarrhoea and enteritis	..	158 to 120
General paralysis of the insane	..	39 to 21	Cirrhosis of the liver	..	47 to 30
Infantile convulsions	..	53 to 22	Diseases of pregnancy, childbirth, and the puerperium from 1934	4 41 to 3 13	
Valvular disease of the heart (a steady fall from 1930)	..	681 to 516 (in 1930)			

The following diseases show a definite rise:

Diabetes	..	126 to 178	Leukaemia	..	16 to 23
Osteo-arthritis	..	63 to 84	Lymphadenoma	..	12 to 15
Malignant disease	1,376 to 1,533		Paratyphoid	..	28 to 39
Diseases of the myocardium	..	772 to 2,040	Gastric or duodenal ulcer	..	101 to 112
(A steady rise due chiefly to myocardial degeneration)	..		Divericulitis	..	4 to 14
Exophthalmic goitre	..	24 to 41	Spina bifida and meningocoele	..	20 to 28
			Diseases of the prostate	..	159 to 243

Does this summary give cause for self-congratulation? Many of the falls in rates are due to better use of medical knowledge, applied to sanitation and food and treatment. Many of the increases in rates are due to the rising age of the population, but also to improved diagnosis, because there is registered a paradoxical fall in people dying of old age from 579 in 1927 to 414 in 1937. Where does our civilization go wrong? In food? In agriculture? Such are the questions raised by Sir Henry Tidy's article.—I am, etc.,

Southampton.

E. S. A. KOSCHANSKY.

## "Departmental Prescription"

SIR.—Why on earth do you keep on snarling at the Minister of Health? Your editorial on departmental prescription is the latest of a series of articles in which every effort of the Minister to plan and act for the benefit of the community is at best depreciated and at the worst so greeted as to try to make the public think that he is their worst enemy. The B.M.A. Council's suggestion that the health service proposals found their first inspiration in a desire to control an independent profession in order to control medical certification is most

offensive, and similar innuendoes are to be found in many of its criticisms.

You don't seem to realize that the Minister is working in the interests of the community, and that those of the doctors are of small importance in comparison. I quite believe that your view of these interests may be different from his, but you must give him credit for a single-minded belief that his proposals are in the public interest. After all, he is advised by expert medical men.

The pamphlet on diets for patients with peptic ulcer is to my mind perfectly harmless and very useful. It may refresh the minds of some doctors whose *B.M.J.s* pile up unopened in a corner of the surgery—there are many such, I fear—and besides contains many helpful hints on wartime variants of the essential dietary. I would welcome similar notes on, for example, the early symptoms of pulmonary tuberculosis in adults and children, and there are other subjects I could name where some such advice would be desirable. It is nonsense for you to call a Public Relations Department "in effect a Government advertising agency," and if certain doctors do not like such suggestions being made to them there is always at their elbows the W.P.B. They may do good and in any event can do no harm.

You carp, too, at the requirement for practitioners to submit to the local food office evidence of the necessity for special foodstuffs in certain diseases. It seems to me perfectly rational when the foodstuffs are in small quantity. Twice within the last month mothers of children with coeliac disease have asked me for certificates of stool analysis that their children may get a ration of dried banana. I had these analyses made three years ago, but the children are well on the way to recovery, and I refused the certificates, which means that the banana powder is available for two acute cases. Here again your attitude is a travesty of what it should be.

The Minister may be misguided, but at least you should give him credit for a whole-hearted desire to do his best for the commonality. Do, I beg you, cease to inflame the minds of the profession against him and his proposals. We were landed in a mess in 1911 by such counsels and came out of it with our professional tails well between our legs. I see with dismay and dread the same unreasoning opposition growing and the same debacle approaching. The whole is always greater than the part.—I am, etc

Conventry

W. FRASER ANNAND.

SIR.—How right you were to call attention to the ousting of Aunt Sally as the symbol of unpopularity in favour of the bureaucrat. Surely a much uglier phenomenon and a far more worthy target for brickbats!

The whole country appreciates the work of the Ministry of Food *qua* Ministry of Food in feeding our people under most arduous conditions during five years of war. But the Ministry of Food *qua* medical tutor magnifies its office, and should have reflected for a moment before issuing the leaflet on "Diets for Patients with Gastric and Duodenal Ulcers," which is more suitable for patients than for experienced practising medical men, who do not need to be told that curries and condiments are bad for such patients. Nor, strange though it may seem to the Ministry of Food, do they need to be told that proteins are body-building foods, etc.

It is noted that the Ministry does not advise administration of vitamin C in the form of ascorbic acid, which those of us who see and treat large numbers of such cases prefer to purées and other forms as being convenient and more effective. Fresh vegetables, however prepared, are bulky, apt to cause flatulence, and, at a time when all households are short-handed, require some amount of time and skill in their preparation. Moreover, the vitamin content is inconstant and depends on careful cooking.

It is observed from the leaflet Med. 1 that practitioners with large tropical experience, possessing special qualifications in tropical medicine, are not allowed to diagnose amoebiasis or bacillary dysentery, even though they may have isolated the parasites. They are required to call in the medical officer of health, who may be entirely without clinical experience of either, because only he is competent to certify. Neither are such practitioners considered capable of diagnosing sprue, even

though they may have seen and treated more cases than the whole of the "medical advisers" put together.

The position with regard to diabetes is interesting. Any practitioner is considered capable of diagnosing it, and no distinction is required between glycosuria due to low renal threshold and that which is truly pancreatic in origin. Is this due to omission or is it a complimentary gesture to the G.P.'s skill in clinical pathology?

Certain conditions in Schedule D of Med. 1 are reminiscent of the old quack medicine advertisements. They call for "detailed statements," blood-sugar estimations, lists of symptoms, description of tests carried out, and, in two cases, require "admission to a hospital for a few days at the patient's own expense," where the patient must undergo a "comprehensive test." If he is not prepared to do this he is denied the necessary article of food. All these clinical data are set down in writing and forwarded to the local food officer (!), who forwards them to the Ministry of Food, who submits them to "the medical advisers." When the Ministry of Food receives a "favourable decision" arrangements are made by returning the necessary documents to the local food office, but it is stated somewhere that there is any obligation on the latter to notify the patient that his prayers have been answered. Moreover, when the inevitable delay and procrastination inseparable from official correspondence are considered, some idea may be formed of the length of time this typical procedure is likely to take; and it must be understood that during the period of waiting no emergency interim issue of the food applied for is permitted.

In medical practice any doctor who professed to diagnose disease by correspondence without clinical examination would be regarded, and rightly so, as a charlatan and guilty of "inamous conduct in a professional respect." His chances of being struck off the *Register* would be quite favourable.

Bureaucrats, or as you prefer to call them "administrators," are becoming increasingly prone to interpose themselves between the doctor and his patient as the date for discussion of the White Paper approaches. They are playing a very dangerous game and they will be well advised to keep out of it. —We are, etc.,

### Character and Personality in the Medical Student

SIR.—Dr. E. D. Broster (May 27, p. 729) appears to be bewildered by the changing world around him, his bewilderment expressing itself in a disjointed cynicism.

He refers to the "apotheosis of the so-called under-dog" and the "belittlement . . . of eminence." He suggests that the attempts to enlarge the field of recruitment of doctors will add to the ration of "general bemusement." This is all due to the failure to grasp at fundamentals. Then he attempts to name a few of these, claiming at the same time that "millions of pounds are wasted annually in an effort to inculcate traits of character which are hereditarily non-existent . . . which are promptly and effectively annulled in any home where ignorance, stupidity, idleness, dirt, and vice are the pattern." If millions of pounds are in fact thus wasted each year, this statement must include a considerable proportion of the working-class homes of the country as those where ignorance, stupidity, etc., are the pattern. If it was not intended to include a large proportion of homes, then the amount wasted cannot amount to millions of pounds, so that the statement is either a curious condemnation of the standard of life and culture of the working class or else it is a meaningless exaggeration. In fact, it is doubtful if proportionately any more is wasted in trying to educate the working classes than in trying to educate those of a "certain high standard of living."

Your correspondent then claims that "if the laws of heredity have any validity at all . . . the most fruitful field of higher civilization is little likely to be found in the worst types of home." Again, "the Government, in obedience to the lowest amour, gives almost direct encouragement to the least worthy to reproduce themselves in the greatest numbers and a corresponding discouragement to their betters." Apart from the ques-

tionable accuracy of this last statement, there is implied another gross libel—that those of "a certain high standard of living" are "of the best stock," and "better" than those who have neither "wealth nor position" (this last term being admittedly a "dangerous side issue"). It is true that the wildness and scope of the generalization reduce its value; in fact, it is doubtful if it has any value at all, it being self-evident that in character, common sense, and general intelligence members of the "lower" working classes have few equals. Certainly you will never find a more burning desire for knowledge and culture among the more privileged classes than among the working classes, even if only because these are out of reach of the latter. Any attempt to classify those without worldly social advantage as inferior to those with them can only be the result of inaccurate observation and a peculiar idea as to what makes one superior or inferior.

Apparently Dr. Broster's fears arise because "the laws of heredity and breeding of the best stock are being ignored, and Nature flouted by man himself in relation to himself"; also because the Government is trying to produce a nation recruited from the "worst types of home," a policy which cannot end "but in the deterioration of the race." But this is not all. Even "eminent men not infrequently marry empty-headed women, and succeeding generations deteriorate." This is most alarming because, as Dr. Broster says, these are the very men who can arrest "the deterioration of the race." Furthermore, "individuality, personality, and character are being ironed out and gradually we become a race of automats." Finally, if you can face a further horror, ". . . the medical profession is to become the chattel of politics."

There is no more to be said. Evidently the ability to observe, think, and write clearly has been lost with the ability to "grasp at fundamentals."—I am, etc.,

Parke Frewett Hospital.

H. E. VICKERS.

### Colonial Medical Service

SIR.—I hope I am not too late to add my testimony to the good work and the efficiency of the Colonial Medical Service. I had the privilege of seeing something of its organization on the administrative side during my time in the Colonial Office, and of the quality of those who were accepted for the service. I have also seen it in actual operation in a number of Colonies, and during my visit to a mandated territory I came under the care of its personnel as a patient, when I received the very best care and skilled attention. Both doctors and nurses are a credit to the Service, and it is most unfortunate that an ill-considered and inaccurate comment on its merits should have been given such wide publicity.

The only fault of the Colonial Medical Service is that it is too small. In every territory its members are overworked, and are not sufficient in numbers to cope with the need. It has already established a fine tradition, and it only needs extension on the same lines to fit it more adequately for its great task. It is to be hoped that its members will be assured that the devoted and efficient service of its doctors and nurses is appreciated most by those who know best what has been and is being done.—I am, etc.,

London, S.W.1.

T. DRUMMOND SHIELDS.

SIR.—Perhaps I may be allowed to inform B.M.A. members that the absence of a reply from me in the *Journal* apropos of the attack on me by Lord Hailey and others does not imply my death or any weakness on my part, but is due solely to the fact that my rejoinder has been denied publication on the ground that it is "quite unsuitable for publication in our *Journal*—or indeed anywhere—on account of the violent personalities it expresses"! Apparently the ennobled and the knighted and one other can attack me with impunity, but censorship bars my reply.—I am, etc.,

London, N.W.6.

Dr. R. E. G. Armattoc, director of the Lomeshie Research Centre for Anthropology and Human Biology, and honorary physician in charge of Brooke Park (E.M.S.), Londonderry, has been elected a Foreign Member of the American Association of Physical Anthropologists, and a Patron of the Free German Institute of Science in London.

'TABLOID'

# 6 OXYLAN<sup>®</sup> DIPHENAN

for the treatment of threadworm infestation

'Oxylan' brand Diphenan (*p*-benzylphenyl carbamate) is an anthelmintic of proved efficiency in oxyuriasis. It is not merely a vermifuge, but by its toxic effect on the parasites, inhibits their reproduction. Reinfection is thus minimised since ova are no longer deposited in the anal folds.

'Oxylan' brand Diphenan is well tolerated by

both children and adults, and is free from undesirable side effects. The usual course for adults and children over ten years is one to two products three times a day for one week, with aperients. In persistent cases it may be repeated after seven to ten days. Proportionately smaller doses may be given to children under ten years of age.

Compressed products, each containing  $7\frac{1}{2}$  grains. Bottles of 20, 4s. 0d. (Purchase Tax 6d. extra).  
Bottles of 100, 18s. 0d. (Purchase Tax 2s. 3d. extra). Subject to Medical Discount

Boxes of 12 x 2 c.c. Ampoules : 1% and 2% Solutions.

ARMACEUTICAL MANUFACTURING CO., LTD., THE LABORATORIES, CHELTENHAM, GLOS.

## OBITUARY

## Obituary

By the sudden and untimely death on May 14 of Dr. GUSTAV WEBER THOMPSON, Wellington, Salop, the profession in Shropshire loses, at a time when such can ill be spared, one of its doughtiest champions and most forthright spokesmen. After a distinguished career in India which gained for him the decoration of Commander of the Order of the British Empire, Thompson came to practise in Wellington some fifteen years ago, and during that time not only built up a fine practice but had become an acknowledged leader of the local profession. A keen committee man, he was a Freemason and Royal Society member of the council of the Shropshire and Mid-Wales Branch of the B.M.A., and a member of the County of Salop Police and Finance Committee; he took an active part in the management of most of the local medical charities and of the Wellington College Hospital. It was largely his initiative and energy that brought about, shortly after the outbreak of war, an amalgamation of the medical practices in the town of Wellington, an experiment in group practice that is likely to remain as a permanent memorial to its principal founder; in the early months of this year he took a prominent part in the reorganization of the town nursing services. Thompson's generous and energetic will be sorely missed, a certain brusqueness of manner and vehemence of speech cloaked a nature kind, sensible and generous; he was truly beloved by his patients, and many beside the writer know that they have lost a staunch and true friend.—W. R. H. P.

## Medical Notes in Parliament

Legislation on N.H.S.: No "Absolute Guarantee"

On June 6 Sir E. GRAHAM-LITTLE asked the Minister of Health whether, as he had postponed, *sine die* negotiations with the medical profession regarding the proposals of the White Paper, he would give an assurance that he would not introduce in Parliament any Bill dealing with these proposals until those negotiations were completed. Mr. WILLINK: I recognize that the discussions, which I am, of course, ready to start at any time, will have to be delayed owing to the postponement of the reasons connected with the war, of the proposed conference, the profession. My desire to hold these discussions before introducing legislation is in no way altered by the postponement, even though I am unable, in view of the many uncertainties, to give so absolute a guarantee as Sir Ernest Graham Little suggests in his question.

On June 8 Dr. HOWITT asked the Minister of Health, in view of the postponement of the Annual Representative Meeting of the B.M.A. at the request of the Government, to give an assurance that legislation on a national health service would not be introduced by him until after negotiations had taken place between him and the medical profession, bearing in mind that under its constitution only the Representative Body of the B.M.A. could determine the Association's policy. Mr. WILLINK said he could not give an assurance quite so absolute. It was said he could not give full discussions with the profession before introducing legislation. He saw no reason why he should be prevented from doing so by the delay which would be caused by the profession's inevitable postponement of its conference.

## Colonial Medical Service

In the House of Commons on June 6 Col. OLIVER STANLEY, Secretary of State for the Colonies, opened a debate on colonial administration and plans for the future. He said that the basis of the planning machinery he had tried to set up was, first of all, a colony development committee. That was now in force in nearly all the big Colonies. Its make-up must vary in each Colony, and it must include the heads of the various departments, because they were the people who would put up the detailed planning, it might be of health services or of agriculture. The important subjects of research and medical policy would have to be discussed on another occasion. Medical policy was the twin pillar of education in the new colonial foundation.

Col. Stanley said he wanted to refer to a recent speech made by Dr. Morgan, who was not in his place in the House that day. He had thought Dr. Morgan was so interested in

colonial development that it had never struck him that he would not be present. Therefore he had not given Dr. Morgan any notice that he would raise this matter, and he thought a wise compromise would be that he (Col. Stanley) should relate the facts and postpone the comments which otherwise he would have felt entitled to make. Dr. Morgan, speaking in quite another debate—that on the National Health Service—without any warning to him (Col. Stanley) and for no reason that he could see, and certainly for no reason that hon. members that gave, suddenly told the House—"I can tell hon. members that the Colonial Medical Service is a disgrace."

Of course, added Col. Stanley, they all knew Dr. Morgan who was, he always thought, rather like his famous medical predecessor, Dr. Jekyll. At times Dr. Morgan offered quite cogent and constructive suggestions, but there were intervals when his interjections were, to say the least of it, irrelevant and irresponsible. This occasion was a case with Dr. Morgan he would say, of the Hyde side out. Words spoken in the House went out to an immensely wide circle. Dr. Morgan's remarks went out with no explanation or justification, the caused, as he (Col. Stanley) knew, great bitterness of feeling among many people who were themselves affected in the matter, and there was no justification for them. The Colonial Medical Service had had many difficulties to grapple with, and had often been short-handed and short of funds, but that was not its fault. For the members of the Colonial Medical Service he had nothing but admiration and gratitude for their self-sacrificing efforts on behalf of the colonial territories.

Dr. HADEN GUEST expressed regret that Dr. Morgan was not present. He was a parliamentary and medical colleague of his, and it would have been better if Col. Stanley had quoted the exact words which were used. If Dr. Morgan had said that the medical services in many of the Colonies were—putting in a different adjective—very inadequate, he thought Col. Stanley would have thoroughly agreed with him. It was well known that the medical services were inadequate. He had discussed this matter with Dr. Morgan, and thought that that was really what he meant.

Col. STANLEY said that that might be so, but Dr. Morgan did not say it. His actual words were: "The Colonial Medical Service is one of the worst in the world. I represent the colonial doctors on the British Medical Association in certain parts of the world and I can tell hon. members that the Colonial Medical Service is a disgrace."

## The Services

Col. R. Errington, C.B.E., M.C., T.D., T.A., has been appointed an Honorary Physician to the King and Col. (Temp. Major-Gen.,) Sir E. M. Cowell, K.B.E., C.B., D.S.O., T.D., T.A., an Honorary Surgeon to the King in succession to Col. F. Whalley, C.B.E., D.S.O., T.D., and A. R. Moodie, T.D., late R.A.M.C. (ret.), respectively.

Col. (Temp. Brig.) J. C. A. Dowse, C.B.E., M.C., late R.A.M.C., has been appointed a J. M.S. with the acting rank of major-general. Temp. Surg. Lieut. J. J. Hood, D.S.C., R.N.V.R., has been mentioned in dispatches (posthumously) for gallantry in going to look for wounded below decks when a merchant ship was torpedoed.

## DEATHS IN THE SERVICES

Major-General HOWARD CARR, C.B., M.D., M.Ch., A.M.S. (ret.), died on May 23 at Southampton at the age of 80. He was educated at Queen's College, Cork, and took the M.D. of the Royal University of Ireland. He entered the Army Medical Service, as it then was, in 1884 and saw much active service during his long period in the Army. He took part in the Burma campaign of 1885-7, the Miranzzai expedition of 1891, the Dongola campaign of 1896, the Nile expedition of 1898, the South African War in 1900-2, and lastly in the war of 1914-18. During his active career he appears to have received seven medals and was twice mentioned in dispatches, and in 1915 he was awarded the C.B. for his good work in the responsible post of D.M.S. on the lines of communication in France. He retired in 1919, lived at Netley on Southampton Water, and indulged in his favourite sport of yachting as a prominent member of the Royal Southern Yacht Club.

## CASUALTIES IN THE MEDICAL SERVICES

Wounded.—Temp. Major R. Bolton, M.B.E., R.A.M.C.  
Prisoners of war.—Temp. Major H. M. S. G. Beadnell and War Subs. Capt. J. W. Goronsky, R.A.M.C.  
Prisoner of war.—War Subs. Capt. A. Berkeley, R.A.M.C.

the only possible dangers to his wife and prospective children are (1) that the father subsequently develops tuberculosis of the lungs and infects them; (2) in certain families there seems to be a poor resistance to tuberculous infection if it is met. From the information given there is no reason to suspect the latter. As it is six years since his contact died it is unlikely that the patient will develop pulmonary tuberculosis himself from this source. As safeguards, he could have his chest x-rayed each year, and should keep up a high standard of general health. No special precautions are necessary for the wife and children.

#### Treatment of Ringworm

**Q.**—What is the best modern treatment of ringworm of (a) the head, (b) the body in children? How long does it take to cure?

**A.**—Ringworm of the head—that is, the infection of the hair on the scalp in children—is best treated by x rays by the approved technique, a matter for the expert only. This is a mechanical procedure causing the diseased and healthy hair to fall out, thereby ridding the patient of the infection. It should be noted that ringworm of the head dies out at puberty, and that x-ray treatment is contraindicated in the inflammatory form of the disease. The hair has generally fallen out in four weeks, and when this has occurred complete cure may be assumed. The slight risk of permanent alopecia, usually limited to a small area, has to be taken into account. Acetate of thallium, given in one dose by the mouth, also a means of obtaining mechanical depilation, is not favoured in this country.

Body ringworm in children presents an easier problem because the fungus can be reached and destroyed by external agents. Three applications of the mild tincture of iodine are often curative in suitable cases; brilliant-green solution or gentian violet, 1%, provides an alternative. Daily application of a 3% benzoic and salicylic acid ointment cures in one to three weeks. It is essential to avoid over-treatment, which often misleads by producing a patch of traumatic dermatitis resembling the original lesion.

#### ? Pituitary Obesity

**Q.**—A man aged 27 has noticed a gradual increase in weight during the last four years, from 229 lb. to 248 lb., in spite of intermittent diets. His main complaint is that he is easily dyspnoeic. He has occasional dull headaches, but no vomiting or change in vision. Examination of the various systems reveals nothing abnormal except for generalized obesity. B.P., 160/80. Exercise tolerance test: 100, 164, 136. Dyspnoea, +. Glands normal. Skin smooth and moist. Radiological report: abnormally small pituitary fossa in relation to the skull. Diagnosis, pituitary obesity. Please advise regarding diet and endocrine therapy.

**A.**—The history is suggestive of an intracranial lesion in the neighbourhood of the third ventricle, and complete neurological and ocular investigation should be undertaken. If all investigations are negative, a diet of 800 calories daily, and thyroid extract by mouth to the point of tolerance, as judged by pulse rate, should be tried. Pituitary gland by mouth has no effect. The case should be reviewed periodically, even if investigations are negative.

#### Unusual Syndrome

**Q.**—A patient six months after a normal delivery, at the age of 25, developed a distressing urinary frequency accompanied by retching or vomiting. The latter stops at once as soon as the urine (usually a small amount only) is passed. The symptom is most marked in the early morning. Gynaecological and urological examination reveals no abnormality. At first there was loss of weight and asthenia as well, but these have improved. How should one treat such a case?

**A.**—This is an unusual combination of symptoms. The question cannot be answered without first arriving at a diagnosis. General medical examination, gynaecological examination under anaesthesia, cystoscopic, bacteriological, and possibly radiological examination are all indicated.

#### Smell and Sex

**Q.**—A young woman of 27, married, complains that her husband is very distressed on account of a strong, unpleasant smell which he notices at the time of intercourse. She herself does not smell anything objectionable and thinks the husband is "imagining." Another woman, 39, married, no children, says that her husband refuses to have intercourse for a similar reason. Both women are clean, healthy, bathing frequently and always before intercourse. Both husbands are healthy; there is no history of venereal or any other disease in either. What is the cause? What is the treatment?

**A.**—The question does not indicate whether the smell comes from the mouth, or from the genitals, or from the body. It is obvious that dental sepsis and gastro-intestinal disorders should be excluded, though they are unlikely to be the cause. All human beings give off some odour, usually imperceptible, but, judged by the performance of the bloodhound, quite characteristic for the individual.

Nevertheless, it is probable that the real explanation of the complaint is that given by one of the wives, who postulates that her husband is "imagining." Sexual intercourse in animals is closely associated with the functioning of the sense of smell, and infantile fantasies about sex are associated with the anus rather than with the vagina. An investigation of the husband's attitude to women and sex might prove illuminating and therapeutically helpful. Perfume has been used by women from time immemorial for the purpose of attracting the male, as well as for aesthetic reasons, and the use of scented bath salts might be of value as substituting something positive and pleasant for the unpleasant fantasy the man may have.

#### Malignant Prostate

**Q.**—A patient aged 60 had his prostate removed a year ago. He never regained proper use of his bladder, and 9 months later the surgeon who inserted a de Pezzer stated that the bladder was "half full of growth." He also had pain and marked weakness in one leg suggestive of a secondary growth in the spine. He received 1 mg. diethyl stilboestrol in oil intramuscularly for two months, and has received a tablet of the same strength since for six weeks. He has greatly improved and is no longer bedridden; he can walk two miles, the leg weakness having completely disappeared. Lately on taking his tablet of stilboestrol he has been troubled with rather severe pain in the neck of the bladder, and some drops of urine are simultaneously passed per urethram. What strength of stilboestrol should be administered and for how long?

**A.**—It is assumed that the prostate removed a year ago contained a malignant focus, and that there is some infiltration of the bladder neck. Although the patient complains that the pain comes on after taking his tablet of stilboestrol, it is unlikely that this is responsible for it. It is far more probable that the pain is due to bladder infection and the existence of growth. The administration of stilboestrol must be continued indefinitely. There is no advantage in giving it as an injection, as it acts equally well by mouth. He is receiving less than the usual dose, and two tablets a day should be tried. The indication for reducing the dose is usually soreness of the breast.

## LETTERS, NOTES, ETC.

#### First Aid

Col. C. M. FINNEY (Bearsden, Dunbartonshire) writes: The correspondence on this subject seems to be resolving itself into an argument between those who criticize the St. John first-aid manual and those who regard it as holy writ. Surely a practical outlook is required. Considering that the manual was last revised before the present war it has surprisingly few real errors, and is an excellent outline of the subject. But there appears little necessity for slavishly following all it contains. I have been giving lectures on first aid for many years both in and out of the Army, and have always tried to get the classes to realize that the subject is essentially a practical one, and to teach them methods which they are capable of carrying out under the conditions of total warfare. Anyone may be called upon to deal with a casualty, and should know what to do and what not to do. The study of first aid is to enable the student to help save life and limb, not to pass examinations. But a candidate who has a sound practical knowledge of the subject is not likely to fail in an examination, even if his answers are not strictly in accordance with the manual. Where the latter differs from what I consider to be the correct line of treatment I warn candidates that possibly a "book" answer may be expected by the examiner. Where instruction is given by a lay lecturer it may be wise for him to follow the manual, but I suggest that a medical man should be familiar with the latest advances in first-aid treatment, and should be able to give instruction to his class such as will enable them to be of real help to the community when called upon to deal with a casualty.

#### Byssinosis

Dr. JOHN C. BRIDGE (London, S.W.1) writes: In case any reader should imagine that the disease byssinosis is subject to compensation to workers in a woollen mill, as suggested in the answer on page 737 of your issue of May 27, may I point out that compensation is strictly limited to male workers in certain specified occupations employed in cotton card-rooms or other specified parts of factories engaged in the spinning of raw cotton and have been employed for periods amounting in the aggregate to not less than 20 years. No such disease has been described as occurring in workers in woollen mills.

#### Prevention of Industrial Dermatitis

Dr. N. HOWARD MUMMERY informs us that since the publication on May 13 (p. 660) of his memorandum on "Prevention of Industrial Dermatitis" he has received a large number of letters from doctors in industry asking where they can obtain the cleansing mixture to which he referred. Arrangements, he says, have now been made by which the mixture can be supplied on direct application to Messrs. Reynolds and Branson, Ltd., 13, Briggate, Leeds, 1.

LONDON SATURDAY JUNE 24 1944

## AN EXPERIMENTAL STUDY OF DIFFERENT METHODS OF ARTIFICIAL RESPIRATION

BY

A. HEMINGWAY, M.Sc., M.B., Ch.B.

*Professor of Physiology*

AND E. NEIL, B.Sc., M.B., Ch.B.

*Demonstrator in Physiology*

(From the Department of Physiology, School of Medicine, Leeds)

Two articles have appeared recently (Cordier, 1943; Eve, 1943) in which the criteria of efficiency of different methods of artificial respiration have been discussed. The aim of all methods of artificial respiration is agreed upon—it is the maintenance of respiratory exchanges in the nervous system. For this to take place two fundamental requirements must be fulfilled (a) adequate pulmonary ventilation; (b) transport of respiratory gases from and to the lungs. Cordier devotes attention to the first of these fundamentals, while admitting the importance of the other, and reviews the experimental evidence for the claims of efficiency made for Schäfer's, Silvester's, and the rocking (Eve's) method. He concludes, basing his judgment on lung-ventilation measurements, that the rocking method is not necessarily superior to other methods despite the claims which have been made for it. Eve reiterates the claim (Killick and Eve, 1933) that lung ventilation with the rocking method is equal to that with Schäfer's when measured in a normal subject voluntarily suspending respiration. It is also argued, chiefly on theoretical grounds, that the rocking method is likely to have a more beneficial effect on the circulation than Schäfer's method would have. Both authors, however, stress the necessity for further investigation into the effects of artificial respiration on the circulatory system and the transport of oxygen. Such investigations were actually in progress at the time of publication of those articles, and a preliminary account of them is given in the present paper.

It has been assumed that the fundamental fact to be considered in assessing the value of methods of artificial respiration is the amount of  $O_2$  which can be transported to and used by the tissues. Accordingly, the rates of  $O_2$  uptake, tidal air, ventilation volume, arterial blood pressure, and cardiac output have been measured with different methods of artificial respiration.

## The Animal Preparation

One of the greatest obstacles to the experimental investigation of methods of artificial respiration is the lack of a suitable experimental subject. Because methods of artificial respiration are usually required for their application to man, the human subject is the most desirable. But the use of an individual voluntarily suspending his respiration, or rendered apnoeic by voluntary hyperpnoea, is attended by many objections, which have been discussed by Haldane and Priestley (1935), Henderson and Turner (1941), and Cordier (1943), amongst others. The rigidity of the ordinary cadaver makes it an unsuitable subject, and it is easier to suggest the employment of the warm non-rigid cadaver of a previously healthy individual than to undertake it; nor is it possible to investigate circulatory conditions in these circumstances. Anaesthesia carried to the point of depressing the activity of the respiratory and vasomotor centres would appear to give an ideal condition for experiment, and Waters and Bennett (1936) and Macintosh (1943a) have recently described a near approach to it in experiments in which anaesthetized persons were rendered apnoeic, by forced ventilation, for a sufficiently long period to allow tidal air volumes to be measured under different methods of artificial respiration.

Since there did not appear to be any methods by which a suitable human subject could be employed for periods long enough to enable extensive measurements to be made on the cardiovascular system, it was decided to use dogs, either with a spinal transection made between the first and second cervical segments, or deeply anaesthetized with nembutal so that the medullary centres were inactive. For the latter preparation nembutal (1% solution in isotonic saline) was injected intraperitoneally until respiration ceased and arterial blood pressure fell to 50–60 mm. Hg. In either case artificial respiration was maintained by a pump except when manual methods were being investigated. Preparations of this type can be kept in good condition over long periods by artificial respiration, and it is considered that they offer good opportunities for comparing the efficacy of different methods of artificial respiration. The medullary centres are inactive and muscle tone is low.

Measurement of Tidal Air and Rate of  $O_2$  Uptake

Rates of  $O_2$  uptake and volumes of tidal air were obtained by a recording spirometer. A Y-shaped cannula was tied into the trachea and a positive-pressure artificial respiration pump could be switched in or out of the spirometer circuit by a system of taps.

## Methods of Artificial Respiration Employed

(a) *Pump Respiration*.—This was instituted immediately before making the spinal section or inducing deep anaesthesia, and the pump stroke was adjusted to give what appeared to be the normal ventilation volume, except when experimental procedures were being undertaken. The usual rate of the pump was 10.8 strokes a minute.

(b) *Abdominal Pressure Respiration (Schäfer)*.—The deep thorax of the average dog makes it an unsuitable subject for "prone-pressure" artificial respiration in the orthodox fashion; the prone pressure was unsuitable also for some of the experimental procedures undertaken. But with the dog supine, very firm pressure can be effectively applied to the abdomen and the viscera driven towards the thorax. It is considered that supine-pressure artificial respiration applied in this fashion is quite effective by comparison with prone-pressure respiration, and was abandoned (Schäfer, 1907–8) largely because of the danger of injury to the liver.

(c) *Rocking Method of Artificial Respiration*.—The animal was firmly strapped to a board by its limbs and stops were placed above and below the shoulders to prevent sliding. Rocking was carried out symmetrically about a horizontal axis through the centre of the board. The angle of rock was measured from the horizontal. A rate of 8 to 10 respirations a minute was usually maintained. So far as was possible the movement was made with a constant velocity, and stopping and starting was done fairly abruptly.

## Measurement of Arterial Blood Pressure

Arterial blood pressure was recorded from the carotid or femoral artery. Changes of pressure in the recording system due to alteration of the position of the cannula when rocking was instituted were avoided by using a compensating device.

## Measurement of Cardiac Output

*Application of the Fick Principle*.—Cardiac output was calculated from the formula:

$$\text{Cardiac output (ml./min.)} = \frac{O_2 \text{ uptake (ml./min.)}}{\text{Arteriovenous } O_2 \text{ diff. (ml./100 ml.)}} \times 100$$

The arteriovenous  $O_2$  difference was obtained from analysis of blood samples obtained by arterial and right ventricular puncture. Analyses were made in the van Slyke manometric apparatus. Right ventricular puncture was abandoned after a few experiments because of the technical difficulties during rocking, and subsequently samples of mixed venous blood were obtained by a catheter introduced through

the external jugular vein into the right atrium. Recently a photoelectric cell device, operated on the principle of Kramer (1935) and Appenheimer (1941), has been used for the estimation of the arterio-venous  $O_2$  difference. It has the advantage that 2-3 ml. of blood is withdrawn only temporarily from the circulation and long series of estimations can be made.

Observations

**Effect of Spinal Section on Rate of  $O_2$  Usage.**—After spinal section the induction of deep anaesthesia the rate of  $O_2$  uptake was usually reduced by 25-30%, and the arterial blood pressure had fallen to 40-50 mm. Hg when measurements were made 30-40 minutes later. These points are illustrated by Fig. 1.

FIG. 1.—Rates of oxygen uptake and arterial blood pressure in an animal before and after spinal section.  
○—○ Natural respiration. ●—● Pump respiration (figures under points indicate volume (ml.) of tidal air).  
○—○—○ Arterial blood pressure.

**Relative Volumes of Tidal Air with Different Methods of Artificial Respiration.**—Using the pump for artificial respiration the tidal air volume is determined, within wide limits, by the stroke of the pump and need not be further discussed. When the Schäfer and rocking methods are compared the tidal volume is usually smaller with the former than with the latter. A typical result from some preliminary experiments performed with spinal cats was: tidal air volume with Schäfer's method, 16 ml.; with rocking, 24 ml. In a longer and more satisfactory series of experiments on spinal or deeply anaesthetized dogs a similar relation has been found in the large majority of experiments. In 10 out of 11 experiments the rocking method has given the greater volume of tidal air, and, taking the mean of all experiments, the tidal air with this method has been 54% greater than with Schäfer's. The difference between the tidal air in the two methods has been greatest when deep anaesthesia has been induced. In these circumstances muscle tone has been very low, and the forces responsible for restoring the volume of the thoracic cavity following the expiratory phase of the Schäfer have presumably been weak: the tidal air has often diminished progressively during the period of artificial respiration despite efforts to increase the respiratory pressure. Low muscular tone is not so likely to affect the volume of tidal air in the rocking method, because the diaphragmatic movements in both the inspiratory and the expiratory phases are impelled by the movements of the abdominal viscera. In this respect the experiments give support to the argument advanced by J. J. H. (1942).

**Comparison of Rate of  $O_2$  Uptake with Different Methods of Artificial Respiration.**—The usual course of an experiment was first to record the rate of  $O_2$  uptake with pump respiration. This was done during two or three periods, and pump respiration was then replaced by either rocking or Schäfer's method of artificial respiration. When the necessary observations had been made pump respiration was reinstituted, and after this the alternative method of artificial respiration was applied. In suitable preparations the whole procedure could be repeated. The results of a typical experiment are depicted in Fig. 2. The rate of  $O_2$  uptake with pump respiration was 23-27 ml./min.; artificial respiration by rocking gave a rate of uptake of 26.6 ml./min., and with Schäfer, 16.8 ml./min.

FIG. 2.—Rates of oxygen uptake. Comparison of artificial respiration carried out by pump, rocking, and Schäfer's method.

In some experiments the rate of  $O_2$  uptake with Schäfer's and the rocking method has been smaller than with pump respiration, as is shown in Fig. 3, but on only one occasion has the  $O_2$  uptake with Schäfer's method been greater than it was with rocking, although often there has been very little difference between them.

FIG. 3.—Similar experiment to that of Fig. 2, but showing gradual fall in oxygen uptake with pump respiration throughout experiment.

**The Significance of Tidal Air Measurements in Comparing the Efficacy of Methods of Artificial Respiration.**—Cordier (1943) observes that "the determination of ventilation is only one criterion in judging the efficiency of these methods." Observations of the type given in Table I show clearly that tidal air is not necessarily the determining factor in  $O_2$  uptake, for with very different tidal airs and ventilation volumes there may be similar rates of  $O_2$  uptake. For in this experiment, although tidal air volumes and ventilator volumes by the Schäfer method were only about 50% of those with the rocking method, there was little difference in the rate of  $O_2$  uptake.

TABLE I.—Tidal Air, Ventilation Volume, and  $O_2$  Uptake

Period	Type of A.R.	Tidal Air (ml.)	Rate per min.	Vent. Volume (ml./min.)	$O_2$ Uptake (ml./min.)
1	Rocking	125	10.0	1,250	54.0
2	Schäfer	62	10.0	620	50.0
			40-minute interval		
3	Rocking	125	7.6	950	43.0
4	Schäfer	58	10.0	580	43.3

Unless the alveolar  $O_2$  tension is allowed to fall so low that anoxia supervenes, alterations in the supply of oxygen by changing the tidal air and ventilation volume should not affect the rate of  $O_2$  uptake. That this principle can be applied to the spinal preparation under pump respiration is shown by Fig. 4.

FIG. 4.—Rates of oxygen uptake with alterations in volume of tidal air in animal after spinal section. Figures under points indicate tidal air volumes (ml.).

In this experiment alterations in the volume of tidal air between 100 and 250 ml. had no effect on the rate of  $O_2$  uptake, which fell steadily throughout the experiment. But if, in similar experiments, the tidal air was reduced below a certain volume the rate of  $O_2$  uptake fluctuated with it, as is shown in Fig. 5. Rates of  $O_2$  uptake were measured before spinal section at three different volumes of tidal air, and varied according to the tidal air volume. After spinal section a similar relationship held although the rate of  $O_2$  uptake was lower, and a tidal air of 100 ml. was presumably sufficient to maintain an adequate alveolar  $O_2$  tension.

But it has been observed, in some experiments, that alterations in the volume of tidal air, induced by changing the method of artificial respiration, have been followed by disproportionate changes in the rate of  $O_2$  uptake. The results of such an experiment are given in Table II.

# STUDY OF METHODS OF ARTIFICIAL RESPIRATION

TABLE II.—Tidal Air, Ventilation Volume, and O<sub>2</sub> Uptake

Period	Type of A.R.	Tidal Air (ml.)	Rate per min.	Vent. Volume (ml./min.)	O <sub>2</sub> Uptake (ml./min.)
1	Pump	100	10.8	1,080	23.5
2	Rocking	94	8.4	789	26.6
3	Pump	100	10.8	1,080	23.2
4	Schäfer	73	10.0	730	16.8
5	Pump	100	10.8	1,080	25.8

The agreement between the rates of O<sub>2</sub> uptake during the periods of pump respiration suggests that the condition of the preparation was fairly stable, but respiration by rocking, although resulting in a slightly smaller volume of tidal air than with pump respiration, gave a higher rate of O<sub>2</sub> uptake. During respiration by Schäfer's method the volume of tidal air was reduced to approximately 78% of that with rocking, but the rate of oxygen uptake fell to 63%.

FIG. 5.—Similar experiment to that of Fig. 4, but showing changes in rate of oxygen uptake according to tidal air volume before and after spinal section.

It was clear from the results of this and similar experiments that if the effectiveness of artificial respiration methods was to be assessed in terms of the rate of O<sub>2</sub> uptake, factors additional to tidal air volume had to be considered. Some experiments seemed to show clearly that the O<sub>2</sub> uptake varied with the tidal air; others, such as those shown in Tables I and II, pointed equally clearly to the intervention of other factors. Of these probably the most important is cardiac output, and both Henderson (1937) and Schäfer (1903) make reference to it without, however, quoting any experimental evidence. Another section of this work deals with measurements of cardiac output under different conditions of artificial respiration and with the significance of the findings.

**Effect of the Angle of Rocking on the Volume of Tidal Air.**—Although the volume of the tidal air should not be taken as the sole criterion of the efficacy of a method of artificial respiration, it is necessary to know how the angle of rocking affects the tidal air volume if recommendations are to be made regarding the optimum rate and angle of rocking. Killick and Eve (1933) showed that a human subject voluntarily suspending respiration than rocking to 30°, and Macintosh (1943b) has recently made similar observations on an anaesthetized human subject rendered apnoeic by deep ventilation. In a dog, with respiratory activity suspended by deep barbiturate anaesthesia, the results of rocking to various angles were as shown in Table III.

TABLE III

Angle of Rock	Tidal Air (ml.)
30°	108
45°	156
55°	162

Rate of rocking, 9.5 per min.

Apparently, in the dog, the volume of tidal air is not increased significantly by rocking beyond 45° (see also Fig. 6), and since in the human subject rocking to this angle gives a tidal air similar to that in quiet respiration, it appears to be adequate for artificial respiration.

**Rate and Rhythm of Rocking:** (i) **Rate of Rocking.**—The effect on the tidal air and ventilation volume of rocking at various rates was determined. The results of a typical experiment were as given in Table IV.

TABLE IV

Rate of Rocking per min.	Tidal Air (ml.)	Ventilation Volume (ml./min.)
6.75	146	985
9.50	148	1,405
12.40	144	1,787
16.10	144	2,320

Angle of rock, 45°

The findings are not entirely in accordance with those of Killick and Eve (1933) on the human subject, for they reported that, although there was an increase in ventilation volume as the rate of rocking increased, the tidal volume is practically unchanged over the range of rates of rocking investigated. It seemed likely, having regard to the large ventilation volumes ensuing with high rates of rocking, that CO<sub>2</sub> might be "washed out" and the normal stimulus to breathing so removed. In a dog, lightly anaesthetized, it was found that a period of hyperventilation, either with a pump or by rocking, was followed by apnoea. The results of an experiment are given in Table V.

TABLE V.—Effect of Rate of Rocking on Ventilation Volume and Induction of Apnoea

Period	Type of A.R.	Rate per min.	Tidal Air (ml.)	Vent. Vol. (ml./min.)	Duration of A.R. (sec.)	Duration of Apnoea (sec.)	Rate of O <sub>2</sub> Uptake (ml./min.)
1	Natural	8-25	146	1,203	125	87	82.0
2	Pump	39-60	200	7,800	163	0	79.0
3	Rocking	9-50	145	1,378	135	20	82.6
4	"	12-40	145	1,935	145	27	86.7
5	"	16-10	166-146	2,510			

From the preceding considerations it is obvious that the ventilation volume while rocking should not exceed the normal resting volume if the danger of apnoea is to be avoided; with the human subject, if the usual volume of tidal air in the rocking method is taken as 500-600 ml., the rate should not exceed 10 a minute.

(ii) **Rhythm of Rocking.**—The rhythm of rocking—i.e., the rate between the duration of the inspiratory and expiratory phases—does not appear to be important in considering ventilation volume provided each is long enough to allow entry or exit of an adequate volume of air. The point will be discussed further, however, in connexion with the circulatory effects.

**Effects of Artificial Respiration on Cardiac Output.**—The object of any method of artificial respiration should be to maintain or increase the flow of well-oxygenated blood, at a suitable CO<sub>2</sub> tension, through the tissues of the body and, in particular, the brain. Although there is evidence of some vasomotor control of the cerebral vessels in the conscious or the lightly anaesthetized animal (Forbes and Cobb, 1938) it is likely in such cases, and almost certain when the respiratory and vasomotor centres have failed, that the cerebral flow is governed chiefly by the systemic blood pressure and, *ceteris paribus*, this will be determined by the effects on the cardiac output of a typical experiment in which the effects on the cardiac output of artificial respiration by positive-pressure pump, rocking, and Schäfer's method, respectively, were compared are given in Table VI.

TABLE VI

Period	Type of A.R.	Tidal Air (ml.)	O <sub>2</sub> Uptake (ml./min.)	Blood O <sub>2</sub> (ml./100 ml.)			Cardiac Output (ml./min.)
				Art.	Ven.	Arterio-ven. Diff.	
1	Pump	150	61.1	17.3	12.1	5.2	1,219
2	"	150	62.3	16.7	11.7	5.0	1,218
3	Rocking	104	53.8	16.7	11.2	5.5	979
4	Schäfer	75	56.4	—	—	—	—
5	Pump	150	61.1	17.3	12.1	5.2	1,219

In three successive experiments of this type the cardiac output with rocking was greater than with Schäfer's method, however vigorously the latter was applied (in one experiment post-mortem examination showed that the liver had been ruptured!); but in changes in cardiac output should not be considered alone but in conjunction with the accompanying alterations in the saturation of the venous blood. This was highest during rocking and lowest during the application of Schäfer's method. In general, the cardiac output, measured during relatively short periods of artificial respiration (5-10 min.) to give accuracy in comparison, has been about 25% greater with rocking than with the abdominal-pressure method.

Having established the superiority, under the given experimental conditions, of the rocking method in its effect on cardiac output, further inquiry was made into the effect of prolonged rocking, and of rocking to various angles. The results of an experiment are represented in Fig. 6. Measurements for the assessment of cardiac output were first made during a period when the animal was under light nembul anaesthesia. The anaesthesia was then deepened until the respiratory centre was completely depressed, and artificial respiration by the pump was instituted. During this stage the cardiac output was reduced to less than half of what it had been previously under light anaesthesia. Rocking was then started and maintained for 52 minutes, and the cardiac output compared at angles of rock of 30°, 45°, and 55°. Taking the output when the rocking angle was 45° as a standard for comparison, it is clear that the cardiac output increased steadily during the period; but the final response,

when rocking to 55°, indicates that the maximum output had been almost reached. It is important to notice, in assessing the effectiveness of the artificial respiration, that the output at the end of the rocking period and immediately before returning to pump respiration was only 17% less than during light anaesthesia. The rapid decline in the cardiac output to below the pre-rocking level when pump ventilation was restored shows that the increase in cardiac output was due solely to the rocking. The impossibility of assessing the effectiveness of artificial respiration solely by measurement of tidal air volume is also illustrated; for although, with one exception, the volume when rocking was less than the stroke of the pump, the cardiac output was almost double that with pump respiration.

FIG. 6.—Effect on cardiac output of prolonged rocking and of rocking to various angles. Rocking to 30°, 45°, 55° for the periods indicated on the graph. Figures under points indicate tidal air volumes (ml.).

The percentage oxygen saturation of the mixed venous blood immediately before rocking was 46; at the end of the rocking period it had risen to 73, but 30 minutes after the cessation of rocking it had fallen to 53. Referred to a typical  $O_2$  dissociation curve for dog blood at 40 mm. Hg  $CO_2$  tension (E. Neil), these percentage saturations are found to correspond to oxygen tensions of 28.5, 47, and 32 mm. Hg respectively, and the effect of an increased cardiac output in providing a higher unloading tension of oxygen is demonstrated.

#### Discussion of the Effects of Artificial Respiration on the Circulation and of the Rhythm of Rocking for Maximal Cardiac Output

Only brief consideration can be given to the ways in which the methods of artificial respiration examined—Schäfer, rocking, and pump—affect the circulation. In each case the movements of the body wall and the diaphragm are passive; they are not due to muscular activity. In Schäfer's method the abdominal cavity and contents are alternately compressed and released. During compression the venous return is augmented by the emptying of the splanchnic vessels, but the entry of more blood into the abdominal veins is prevented by the rise in intra-abdominal pressure. When the compression is released and the intra-abdominal pressure falls the splanchnic vessels will fill again and tend to reduce the venous return. Blood-pressure tracings show an increase in mean pressure and a slight increase in pulse pressure during compression; the mean pressure falls abruptly by 10–15 mm. Hg when the compression is released, and the pulse pressure is diminished.

During rocking when the head-down position is assumed, there is emptying of the abdominal and hind leg veins by gravity. The diaphragm moves towards the thorax and the intra-abdominal pressure is diminished. There is no impediment to the flow of blood into the abdominal veins. Arterial blood-pressure tracings show a gradual rise in the mean pressure and an increase in the pulse pressure. When the animal is placed in the head-up position blood tends to accumulate in the abdominal and leg veins, although this may be opposed to some extent by the increase in abdominal pressure as the diaphragm descends. Judging by the pulse pressure, the increase in cardiac output in the head-down position is much greater than in the compression phase of Schäfer, and the *vis a tergo* continues to maintain the venous return during the head-up phase.

The accumulation of blood in the abdominal vessels is likely to be minimal if the duration of the head-up phase is as short as is compatible with the intake of an adequate volume of air into the lungs. According to the findings presented in Table V this can be less than 2 seconds without reduction in

the volume of tidal air. Experimentally, a 6-second respiratory cycle, divided into 4 seconds head-down and 2 seconds head-up has given good results, although a ratio of 3/2 seems slightly better. If the findings are to be applied to the human subject a 7-second cycle—4 head-down, 3 head-up—might be most suitable, taking into consideration the dimensions and inertia of the stretcher and subject, although Killick and Eve's (1933) results show that a tidal air of 500 ml. can be obtained a 13 rocks a minute.

Comparison of the effects on cardiac output of pump respiration with those of rocking or Schäfer's method provides no consistent conclusions. In some experiments, as in that yielding the results for Table VI, pump ventilation has been as effective as rocking in maintaining the cardiac output; in others—e.g. Fig. 6—the pump has been relatively ineffective in this respect. The explanation of these discrepancies is likely to be complex. Factors to be considered are the effects of lung inflation and collapse on the pulmonary circulation (Daly, 1930) and the extent and effects of diaphragmatic movement in different animals; but since they do not affect the comparison of the two manual methods they will not, at present, be considered further.

#### Commentary and Conclusions

It is clear from the results of the experiments which have been described that the oxygen uptake and effective transport during artificial respiration is not governed only by tidal air and ventilation volume. It is therefore impossible to assess the efficiency of different methods of artificial respiration by measurement of tidal air volumes if these differ by only small amounts. It is obvious that more attention should be devoted to an assessment of the circulatory changes which are induced by artificial respiration.

It is concluded that the rate of oxygen uptake and the cardiac output are usually greater with the rocking method than with the Schäfer; the  $O_2$  tension of the venous blood is higher.

The reasons for the differences in oxygen uptake with different methods of artificial respiration are not completely clarified. In any one case it would seem to be necessary to consider the following points: (a) Alterations in the tone of muscles due to stretch reflexes which would entail increased oxygen consumption. (b) If tissues are anoxic then increased oxygen supply to the part concerned might be followed by an increased uptake. (c) The higher rate of oxygen uptake with the rocking method than with Schäfer's method may be due, in part, to the increased cardiac output.

The heart rate in the spinal or deeply anaesthetized animal is constant, and alterations in heart output must be due to changes in stroke volume. In experiments employing the cardiometer, an increase in diastolic volume with rocking has been seen, and this will be associated with an increase in the rate of oxygen usage of the heart (Hemingway and Fee, 1927).

Finally, we are in full agreement with the view (*First Aid in the Royal Navy*, 1943) that the Schäfer method should be immediately instituted when resuscitation is undertaken, and that no time should be lost while preparations are being made for the use of any other method.

We wish to thank Dr. J. McMichael and Dr. A. Schweitzer for valuable suggestions made during the course of this work. A fuller report of the investigation, the expenses of which have been defrayed by the Medical Research Council, is being made to the Naval Personnel Research Committee of the Council.

# THE IMPROVED DENTITION OF 5-YEAR-OLD LONDON SCHOOL-CHILDREN

## A COMPARISON BETWEEN 1943 AND 1929

BY

MAY MELLANBY

(Nutrition Building, National Institute for Medical Research, N.W. 7)

AND

HELEN COUMOULOS, D.D.S., Athens

(Girton College, Cambridge)

### Historical

It is now established that certain nutritional factors play a prominent part in determining the structure of the dental tissues and their resistance to disease. Interest in this subject was first roused by the investigations on animals and children made by one of us (M. M.) which began in 1917 and have continued up to the present time.

### (a) Animal Experiments

It was shown in experiments on puppies and other young animals that perfect and imperfect teeth could be produced at will by small variations in the diet during the period of tooth development (Mellanby, 1918). The chief among these determinants were the fat-soluble vitamins, and especially vitamin D (which in the earlier days was called the calcifying vitamin). This substance acted in association with the calcium and phosphorus of the diet, and for optimum effect required a sufficiency of these elements; in the absence of vitamin D, even large quantities of calcium and phosphorus in the diet did not result in perfectly formed teeth and jaws. A deficiency of this vitamin in the mother's diet during pregnancy and lactation, especially with a low intake of calcium, caused the deciduous or milk teeth, and to a less extent the permanent teeth, of her puppies to be imperfectly calcified, even when, after weaning, their own food contained abundance of these substances; if the puppies continued on the same defective diet as the mother their permanent teeth were very badly formed—more so, in fact, than if the mother's diet during pregnancy and lactation had been good from the point of view of tooth development. It is seen, therefore, that the mother's diet during these periods may to some extent affect the teeth of her offspring for life.

In the living animal, teeth of perfect structure were translucent and felt smooth when their surfaces were rubbed lightly with a probe, whereas varying degrees of roughness were encountered when the teeth were of imperfect structure. It was shown that there was a close correlation between the surface appearance or texture of the teeth, determinable *in situ*, and their minute architecture as seen in microscopical sections made after death.

### b) Investigations on Children

When a large collection of children's shed and extracted teeth was examined and graded according to the standards developed and adopted by M. M. on the basis of the animal experimental work, perfect structure and all grades of imperfection were found, although some 80% came into the latter category. Teeth of good structure were on the whole found to be much less carious than those of defective structure, 8% of the former, compared with 6% of the latter, being caries-free. This relationship, however, did not necessarily apply to the comparatively few teeth with gross enamel defects obvious to the naked eye—forms of dental hypoplasia which used to be, and indeed still are, the only ones generally recognized.

From 1922 onwards a series of investigations on children in Sheffield tuberculosis hospital (1924, 1926, 1931, and 1934) and in three Birmingham Cottage Homes (1934) were made in co-operation with medical and dental colleagues. These investigations showed that those dietary factors which promoted well-calcified teeth also influenced them after full eruption and tended to retard to some extent the onset and spread of caries. Thus there was in the Birmingham study significantly less incidence and spread of caries in a group of children receiving additional vitamin D and olive oil than in the control group getting extra olive oil without the vitamin; for instance, in the permanent teeth already erupted at the beginning of the

investigation, an increase of only 8% of carious teeth was found in the vitamin D group in 2½ years, compared with 13.8% in the control group. Moreover, there was an even greater difference in those which erupted during the actual period of the investigation, the structure of which teeth may have been influenced by the diets (i.e., 7.6% of these teeth were carious in the vitamin D group, compared with 17.8% in the control group). In these series of investigations the most important dietary factors for delaying the onset and spread of decay were milk, cod-liver oil, and irradiated ergosterol (vitamin D<sub>2</sub>). With low vitamin D and calcium it was found that increasing the cereal content of the diet allowed the disease to spread more rapidly than in the controls with comparatively little cereal, probable reasons for this being that there are some anti-calcifying substances in cereals.

The above facts and many other experimental and clinical results were brought together in three special reports of the Medical Research Council published in 1929, 1930, and 1934 (M. Mellanby).

More recently these investigations on the initiation and spread of caries in children's teeth have been repeated and extended in different parts of the world (Anderson *et al.*, 1934; McBeath, 1932, 1934; McBeath and Zucker, 1938; McBeath and Verlin, 1942; McKee, 1930; Schiotz, 1937), so that to-day medical and dental clinicians as well as scientific investigators are realizing more and more that nutrition plays an important part in dental disease. They do not always, however, fully appreciate the long period during which dietetic factors must be operative in order to promote good dental structure and increase resistance to disease. For instance, they often expect results after a few months' administration of cod-liver oil, whereas the treatment should begin in early intra-uterine life and continue during the period of growth, and in a modified way probably throughout life.

The direct cause or causes of dental caries in human beings, as distinct from the predisposing factors, are not yet known, but in the work referred to above there was enough evidence to demonstrate that a great improvement could be obtained if the dietary of pregnant women, infants, and children were changed to one of higher calcifying quality. The teeth of the new generation would then be of better structure and less prone to decay. It seemed, indeed, that such a step must form the basis of any policy likely to lead to mass improvement of teeth—a point of view which has been constantly urged by one of us for many years. The dietetic changes advised were: (1) an increased consumption of milk, eggs, and other foods comparatively rich in calcifying factors; (2) a decreased intake of cereals, such as bread, oatmeal, and oatmeal preparations; and (3) the addition to the diet of cod-liver oil or some other source of vitamins D and A, especially the former.

### (c) National Dietary Changes related to Above Investigations

During recent years interest has become focused on public health in relation to food, and the Government has made a special effort to improve the standard of nutrition of pregnant women, infants, and young children. In the past quarter of a century antenatal clinics and infant welfare centres have been established in increasing numbers to advise on the feeding of both mother and baby. Rickets, so common in the 1920's and earlier, has become comparatively rare in England owing largely, no doubt, to the increased consumption of milk and to the greater therapeutic, as well as the prophylactic, use of cod-liver oil and other substances containing vitamin D. The condition of the teeth of the group of children examined in the present investigation could not have been greatly influenced by school feeding, since the majority did not go to school until they were 5 years old, though a few went to nursery classes or schools; but it is of interest to remember that as long ago as 1906 the London County Council made official arrangements for the supply of school dinners to necessitous children, and in 1910 milk and cod-liver oil could be supplied to children whose home conditions were unsatisfactory or when malnutrition was threatened or present. In addition there were an increasingly large number of other children receiving milk, on payment, as the result of voluntary school milk clubs. Only in 1934, however, when the Milk Marketing Board was set up, was a scheme put into operation to supply milk (at first one-third of a pint and later two-thirds of a pint a day) to children, irrespective of their physical condition, in any part of the

country at the reduced rate of  $\frac{1}{4}$  d. per one-third pint bottle, or free in necessitous cases.

With the war have come other advances: cheap milk, cod-liver oil, and orange juice, and a priority of eggs, have become available to all pregnant and lactating women, to infants, and to young children. Dinners are provided at most schools, and their quality has been greatly improved; their provision no longer depends on financial or medical necessity, but has been developed as part of the Government's wartime food policy, and many parents take advantage of the scheme. Calcium carbonate has been added to bread (7 oz. to 280 lb. of flour), and the nutritive value of all margarine has been improved by the addition of vitamin D<sub>2</sub> and vitamin A.

#### (d) Reasons for Present Investigation

While these steps have been taken with the object of bettering the general nutrition of the community and especially of guarding against diseases of childhood such as rickets and concomitant ills, it is obvious that the changes in the dietary are in the main those which the animal and human investigations mentioned above have shown to be necessary for improving the nation's teeth. It seemed of considerable interest, therefore, to see whether there was any evidence that such an improvement had in fact taken place. Fortunately, it was possible to make an inquiry into the question which would provide an answer so far as children attending L.C.C. schools are concerned, for in 1929 a dental examination of some 1,300 unselected 5-year-old children (i.e., children who had not yet come under the full influence of the school dental service) in these schools was made by one of us (M. M.) for the Board of Education. The surface structure of the enamel and the presence and extent of caries in each tooth were recorded; later some of the findings, together with other records made on the same children, were published by the Board of Education (1931). By using the same criteria and examining the same age group attending these schools to-day it would therefore be possible to see what, if any, improvement had taken place in the intervening 14 or 15 years.

Dr. W. Allen Daley, the School Medical Officer to the London County Council, was approached, and the Council's permission to carry out an investigation was readily given.

#### The Present Investigation

When any school visited in 1929 was closed or was no longer used as an infants' department, one or more other schools in the same neighbourhood, as near as possible to that previously inspected, were taken as substitutes. In addition, a few schools in other districts were visited, but they are not included in the main tables.

In 1929 the schools were divided, with the help of the local Care Committees, according to their level in the social scale. For the purpose of the present investigation, therefore, the Care Committees were again approached, and after consultation they made a rough classification into four grades: but they could not guarantee that their groupings were comparable with those made in 1929, which were indicated by the signs B+, B, B-, and C. Moreover, there is now a greater mixing in the schools than hitherto of children from families of different social and financial levels. This is due to many causes, including the clearance of slums and the building of large blocks of flats, the transference of families from one area to another owing to destruction of homes from enemy action, evacuation schemes, etc. Then, again, the financial status of many families has been altered, either raised or lowered, as a result of the war.

In the present survey the dental examinations were shared by us, the majority of children being inspected by H. C. From time to time during the course of the survey, and especially at the beginning, the teeth of many children were examined separately by both investigators, the two records being compared so that as far as possible the same standard would be kept; this was especially necessary for the grading of structure, in which the personal factor plays a prominent part. We were in agreement in most cases; where differences did occur they were generally small.

Detailed examinations of all teeth were made for signs of M-hypoplasia (see next paragraph), gross hypoplasia (the generally recognized varieties), and caries. Other conditions of the teeth, including their alignment, the presence of mottled enamel, and the state of the gums, were noted, but are not considered in this paper. Since results of the 1929 investigation were given as percentages of children showing varying degrees of hypoplasia and caries, similar figures will be given here. A more detailed analysis of our findings will be published later.

#### (a) The Structure of the Teeth

The standards used for structure were similar to those adopted in the 1929 Board of Education survey, which were evolved from the results of the investigations referred to above. Individual teeth were taken to be of normal or perfect structure when their surfaces were smooth and shiny, like those of the teeth of puppies given a mixed diet relatively rich in vitamin D and containing the necessary calcium and phosphorus. Teeth showing imperfections of surface structure were classified into three grades: slightly defective, defective, and very defective. These types of defects will be referred to as M-hypoplasia, a term first used by J. D. King in 1940 to distinguish them from the previously recognized gross or G-types, which are rarely seen in deciduous teeth. The M-type defects were originally described by M. Mellanby (1923, 1927, 1934), who found that some 80% of 1,500 deciduous teeth were so affected.

The surfaces of the teeth with M-hypoplasia show varying degrees of roughness which are not always visible to the naked eye when the teeth are *in situ*, but can easily be detected when their surfaces are lightly rubbed with a probe; the degree of roughness as indicated by the "feel" of the probe can be judged with practice. A sufficiently reliable clinical assessment of the enamel surface texture is obtained if the test is confined to the buccal aspect of the teeth. When each tooth had been considered separately a general computation was made for the structure of all the teeth of a given child, keeping so far as possible to the method of assessment used in the 1929 investigation but dividing the children into only four groups instead of seven: Good structure, Little M-hypoplasia (1 and 2), Some M-hypoplasia (3 and 4), and Much M-hypoplasia (5 and 6). The figures in parentheses refer to the 1929 grouping. The few cases of gross hypoplasia were included in Group 4.

Although 1,604 children were examined in the main survey and included in the caries incidence tables, 33 of them had lost too many teeth for it to be possible to classify for structure, reducing the number for this purpose to 1,571.

In Table I the structure of the teeth in the two investigations is set out. It is clear that in the 14 years that have elapsed the

TABLE I.—Incidence of M-hypoplasia in Deciduous Teeth

	Total Number of Children	Percentages of Children Showing:			
		None	Little	Some	Much
1943	1,571	1.2	18.1	47.4	33.3
1929	1,139	0	7.8	33.6	58.5

picture of deciduous tooth structure has changed for the better. Even so, there are very few children with a full complement of perfectly calcified teeth; however, in 1943 18.1% had only slight M-hypoplasia, compared with 7.8% in 1929, and there were fewer with much M-hypoplasia—33.3% as against 58.5% respectively.

In Table II the findings are given when the schools are divided according to their estimated social status. There are no great

TABLE II.—Incidence of M-hypoplasia in Deciduous Teeth at the Different Social Levels

Social Grading of School	Total No. of Children	Percentages of Children Showing:			
		None	Little	Some	Much
Highest grade (B +)					
1943 .. ..	190	0.5	25.8	49.0	24.7
1929 .. ..	133	0	12.8	30.8	56.4
2nd grade (B)					
1943 .. ..	582	1.0	14.8	50.2	34.0
1929 .. ..	423	0	9.9	36.4	53.7
3rd grade (B -)					
1943 .. ..	556	1.8	18.0	45.1	35.1
1929 .. ..	190	0	4.7	30.0	65.3
4th grade (C)					
1943 .. ..	243	0.8	20.2	44.9	34.2
1929 .. ..	393	0	5.4	33.3	61.3

differences in these groups in 1943, although the tendency is for the highest-grade schools (B+) to have teeth of rather better structure than the schools in the other three grades, which differ little on the whole. In 1929 there was a suggestion that the quality of structure was worse in the lower-grade schools.

#### (b) Incidence of Dental Caries

For the grading of caries each tooth was examined by probe and mirror and put into one of four categories, as follows:

*No caries* that could be diagnosed as definite caries by our methods of examination: (No radiographs were taken.)

*Slight caries*: Very early and suspected fissure and approximal caries.

*Moderate caries*: Cavities involving destruction up to roughly one-quarter of the tooth crown.

*Advanced caries*: Destruction of more than one-quarter of the tooth crown.

## IMPROVED DENTITION OF LONDON SCHOOL-CHILDREN

in the Subsidiary Survey

Fillings and arrested caries were classified very roughly according to the extent of the crown involved and included as carious. If deciduous molars or canines had been lost it was assumed that they had been extracted for advanced caries, since they should normally be present at the age under review.

When each tooth had been graded separately the children were divided into four groups according to the total amount of caries present: the method of assessment used was as nearly similar to that of 1929 as possible. No caries, Little (1 and 2), Some (3 and 4), and Much caries (5 and 6). The figures in parentheses relate to the 1929 classification, when seven groups were distinguished instead of four.

Table III gives a comparison of the relative amount of caries for the two investigations: 22.4% of the children in 1943 were "caries-free," compared with 4.7% in 1929; and only 29.3% had much

TABLE III.—Incidence of Dental Caries in Deciduous Teeth

	Total Number of Children	Percentages of Children Showing*			
		No Caries	Little Caries	Some Caries	Much Caries
1943	1,604	22.4	25.9	22.4	29.3
1929	1,293	4.7	11.7	20.8	62.8

\* Only 6% of the children in this category in 1943 would correspond with the C6 group (very bad caries), compared with 54% in 1929.

caries, as against 62.8% previously. Actually the improvement is even greater than these figures suggest, because in 1943 only about 6% of those in the "Much" caries group could be classed in the C6 category (very bad caries), compared with 54% in the earlier investigation, which included a number of edentulous children. No amount of caries varied considerably from one school to another; in 1943 the percentages of caries-free children ranged from 5 to 37 and of "Much" caries from 50 to 11.5. In 1929 the comparable figures were 0 to 15.4% and 79 to 19%, respectively.

Table IV indicates that in 1943 there was distinctly less caries in the B+ schools than in the other three grades, which differed little among themselves. In 1929 there was a slight tendency for the amount of caries present to increase from the better to the poorer schools.

TABLE IV.—Incidence of Dental Caries in Deciduous Teeth at the Different Social Levels

Social Grading of School	Total No. of Children	Percentages of Children Showing*			
		No Caries	Little Caries	Some Caries	Much Caries
Highest grade (B+)	193	29.5	28.5	21.2	20.7
1943	147	6.1	17.7	15.6	60.6
1929	596	20.8	27.7	22.0	29.5
2nd grade (B)	480	6.5	11.3	22.6	59.6
1943	569	22.9	23.6	21.1	32.5
1929	210	3.8	10.5	22.9	62.8
3rd grade (B-)	569	19.5	25.2	27.2	28.1
1943	210	2.8	10.5	19.5	67.1
1929	456				

among themselves. In 1929 there was a slight tendency for the amount of caries present to increase from the better to the poorer schools.

## (c) Subsidiary Survey

As already mentioned, a subsidiary survey was made of several schools in districts not visited in 1929. The findings are therefore given separately. The amount of hypoplasia was about the same as that found in the schools in the main survey, but there was less decay: 35% of the children had no definite caries.

TABLE V.—Incidence of M-hypoplasia in the Subsidiary Survey

Social Grading of School	Total No. of Children	Percentages of Children Showing*			
		None	Little	Some	Much
Highest grade (B+)	134	0.8	12.7	61.9	24.6
1943	128	0	14.8	46.1	39.1
1929	262	0.4	13.7	54.2	31.7

The schools all came into the B+ and B- categories. In the former, 135 children were seen, of whom 40.7% had no definite caries and only 11.1% had "Much" caries. The teeth of the 131 children

\* There are children included in this group in whom very early caries was present in two or three teeth, and whom to-day we should probably prefer to include in a separate group between caries-free and little caries; but the standard here used is that adopted in 1929, when so few children were seen with anything approaching a caries-free mouth.

TABLE VI.—Incidence of Dental Caries in the Subsidiary Survey

Social Grading of School	Total No. of Children	Percentages of Children Showing*			
		No Caries	Little Caries	Some Caries	Much Caries
Highest grade (B+)	135	40.7	25.2	23.0	11.1
1943	131	29.0	19.1	25.2	26.7
3rd grade (B-)	266	35.0	22.2	24.1	18.8

in the B- schools were not as good from this point of view as those in the B+ schools, but nevertheless 29% of the children were "caries-free" and 26.7% had "Much" caries. The percentages of "caries-free" children in the individual schools ranged from 27 to 44 and those with "Much" caries from 38 to 8.

## (d) Arrest of Caries

In the Sheffield investigation carried out by one of us (M. M.) in co-operation with Dr. Lee Pattison, and referred to above, a striking feature noted in groups of children having a good calcifying diet was the relatively high proportion of decayed teeth in which the caries was no longer active—in other words, in which the caries had become arrested. Many of these children were examined at regular intervals over long periods, and it was found possible to trace the gradual arresting of the carious process. It is therefore significant that in the present survey typical arrest was found in at least some teeth of 28% of all the children with caries.

## (e) Association of M-hypoplasia and Caries

A close association exists between the quality of a tooth and its resistance to decay, as has been mentioned above. To assess this relationship accurately it is necessary to consider individual teeth, but it was thought that a rough indication might be obtained by correlating the structure of the teeth and the amount of caries per child, taking for this purpose only those cases in which no canines or molars were missing. None of the few children with perfect teeth and under 5% of those with nearly perfect dentition were placed in the two worst categories of caries, whereas 38% of the children with "Much" hypoplasia had also "Much" caries and only 8% were "caries-free." It is interesting to note that 34% of those with "Some" hypoplasia had no caries and 40% had "Little"; this suggests that some post-eruptive influence (direct or indirect) was at work, though it must be borne in mind that these children were under 6 years of age and the molars still had a long period in the mouth in which they might become carious.

## Discussion

The data obtained in this survey show clearly that there has been a distinct improvement since 1929 in the dental condition of 5-year-old children attending London County Council elementary schools. The quality of the teeth is now better; in 1943, 19% of the children had teeth of good structure, compared with 8% in 1929, while the percentages with very defective formed teeth (i.e., teeth with "Much" M-hypoplasia) were 33 and 58 respectively. The reduction in the incidence of dental decay is even more striking: in 1943, 22% of the children were "caries-free," compared with 5% in 1929, while only 29% had "Much" caries in 1943, as compared with 63% in 1929. When the schools were grouped according to social status there was little difference in dental condition as regards both structure and caries between the various grades, though the teeth tended to be rather better in the highest-grade schools in 1943 and in the two highest grades in 1929.

These observations, however, do not show whether the improvement is of recent occurrence or whether it has been gradual in this social stratum of London during the past 14 or 15 years. Since, however, the teeth of the 1943 5-year-old children were in the main formed in the immediate pre-war years and the first year of the war, the cause of the improvement in these particular children must be sought among factors operative at and since that time and contrasted with the conditions in the previous survey were developing. Can the improvement be attributed to the changed dietary referred to earlier, which has increased the intake of vitamin D and calcium by the provision of cheap milk and of cod-liver oil to infants and young children, together with the addition of vitamins D and A to the margarine and of calcium carbonate to the bread or is it due to other unknown influences which have been brought to bear on child life in London during these years? No categorical answer can be given to this question, because there still remains much to be discovered not only about the relation of nutrition to dental conditions but also about the

immediate cause of caries. All we can do in attempting to answer the question is to argue from established knowledge and see to what extent this explains the observations.

It is known that the structure of the deciduous and permanent teeth of young animals is affected by the diet during their period of tooth development, both *in utero*, during lactation, and especially after weaning, when much greater defects in dental structure of the offspring may result from diets poor in calcifying properties. The mother has a large quantity of calcium in her bones and sometimes stores of vitamin D in her body; these substances she undoubtedly sacrifices to some extent to her offspring when she herself is deficiently fed, but these offspring will have little or no stores of vitamin D after weaning, so that a poor calcifying diet taken at this time very soon exerts its baneful influence. The same principle probably applies in the case of the child, and it is therefore very important that the pregnant and lactating woman, and later the infant itself, should have diets rich in the factors necessary for the production of well-calcified teeth.

The experimental evidence that dental structure is largely controlled by the ingestion of enough vitamin D, calcium, and phosphorus is so strong that it is difficult to avoid the conclusion that the improvement in dentition of the 1943 children has resulted largely from the changes in dietary in the immediate pre-war and early war period. If this is the case, and if mothers and children are taking and continue to take full advantage of the additional improvements in dietary that have been placed at their disposal during the last year or two, it seems safe to predict that children's teeth now being formed will be even better than those of the children seen in the 1943 survey.

While, therefore, the reason for the improvement in dental structure seems clear, the cause of the reduction in dental caries is less certain. Since M. M.'s early investigations on children's teeth showed that those of good structure were less liable to caries than those of poor structure, and since the structure of the teeth in this survey was better than in 1929, some reduction in the amount of caries was to be expected from this cause alone. The reduction observed, however, was greater than could be explained on this basis, so that some other contributory factors were evidently at work.

Investigations carried out by M. M. and her colleagues and others have shown that the dietary factors which promote well-calcified teeth also tend to retard the onset and spread of caries, apart from their influence on structure. The dietary of the young children in the 1943 survey has been improved from this point of view even beyond the standard reached during the immediate pre-war period and early part of the war, when their teeth were being formed, and it is considerably better than the dietary at the corresponding period in the lives of the 1929 group of children. It might be surmised, therefore, that the reduction in caries in 1943 as compared with 1929 is due in part to the better structure, which is related to better calcifying dietary, in part to the post-eruptive influence of the even better dietary condition of the war years, and possibly in part to other unknown changes. What these other factors are that may share the responsibility for the diminution of caries in these children can only be conjectured. Some would say that changes in the carbohydrate intake or the fluorine intake or of food consistency, or a greater use of the toothbrush have played a part. Unfortunately the basis of these suggested factors is too insecure at the present time to allow their effects to be assessed adequately.

If the present national food policy has been responsible, as seems likely, for much of the improvement of the teeth here reported, this only emphasizes the importance of still greater efforts on the part of central and local government in the same direction, for even to-day 78% of these 5-year-old children have some decayed teeth. Parents must be taught to realize that the consumption of milk and vitamin D is a *sine qua non* for improvement of the teeth of their children, and they must be induced to co-operate more willingly in this health-giving project. Much has already been done by the staffs of welfare centres, school medical and dental officers, Care Committee workers, and teachers; but unfortunately there still remains a fair proportion of parents who, for one reason or another, fail to take full advantage of the dietary supplements at their disposal.

The facts emerging from this investigation can be regarded as heartening and as providing evidence that we are at last taking steps in the right direction to attack successfully the most widespread of the ills of civilized man. Florid rickets—the cruder manifestation of defective calcification—has been virtually eliminated in England by better feeding of pregnant and lactating women, and of infants and children. It is possible that the elimination of dental caries may not be attainable until its immediate cause is known, but even without this knowledge it is probable that a continuation and extension of the present nutritional policy and its more whole-hearted adoption by the public would bring about further improvement in the architecture of teeth and in their subsequent resistance to decay. It would then at least be possible to present to dental surgeons a situation which they could tackle hopefully.

### Summary

The results are given of two large-scale dental surveys of 5-year-old children in the same or comparable schools of the London County Council in 1943 and 1929.

During the intervening period a great improvement has taken place both in the structure of the deciduous teeth and in their resistance to decay. (a) 19% of the children had teeth of perfect or nearly perfect structure in 1943, compared with 8% in 1929, and only 33% had very defectively formed teeth (i.e., teeth with much M-hypoplasia), compared with 58% in 1929. (b) In 1943 22% of the children were, according to the standards used, "caries-free," compared with about 5% in 1929.

That there is still great room for improvement in dental condition is demonstrated by the fact that even at the present time between 56 and 95% of children in individual schools visited in the two surveys had dental decay in at least some of their teeth.

It is thought that the observed improvement in the dental condition of this age group may be largely due to the changes in feeding habits which have been developing in recent years—in particular to the introduction in 1934 of the cheap milk scheme of the Milk Marketing Board and later to the wartime food policy, which included (a) increased allowances of milk together with cod-liver oil and fruit juices to pregnant and lactating women, to infants, and to young children; (b) the addition of vitamins A and D, to margarine; and (c) the addition of calcium carbonate to bread. These are dietetic changes that investigations on animals and children carried out by one of us (M. M.) since 1917 have established as essential for the improved dental condition of the general child population.

Our thanks are due to many people who have helped us directly or indirectly with this investigation. These include: the London County Council and Dr. W. Allen Daley for their permission to carry out the inspections, for making the necessary arrangements at the schools, and for their kind interest in the progress of the survey; the Care Committee Organizers for grading the schools and for other valuable assistance; and Miss Irene Allen for general help, and especially for working out the results given in the tables. Last, but by no means least, we want to thank the head teachers of the infant schools and their assistants, without whose willing and interested co-operation the work would have been impossible. H. C. holds a scholarship from the British Council, and other expenses were paid by the Medical Research Council; to both of these bodies we are very grateful.

In an address to the Conference of the Children's Nutrition Council (Wales) at Cardiff on May 13, Mr. Eddie Williams reminded his audience that the object of the Council was "to ensure that no child, by reason of the poverty of its parents, shall be deprived of at least a minimum of food and other requirements necessary for full health." He strongly advocated the institution of school meals throughout Great Britain.

# POLIOMYELITIS IN BRITISH AND AMERICAN TROOPS IN THE MIDDLE EAST

THE ISOLATION OF VIRUS FROM HUMAN FAECES

BY  
JOHN R. PAUL, M.D.\*  
W. P. HAVENS, jun., M.D.\*  
(M.C. 1151)  
AND  
C. E. VAN ROOYEN, M.D.  
(M.C. 1151)  
Middle East Forces

Van Rooyen and Morgan (1943) called attention to poliomyelitis as a military disease in the Middle East. Since 1940, cases of this disease among British troops have not been uncommon; many have been severe, and a high percentage have been fatal. From several of these fatal cases (occurring in 1942 and 1943) the virus of poliomyelitis has been isolated by them from the central nervous system, and the properties of some of these strains have also been studied by Schlesinger (1943) in the United States. The present report is concerned with a series of attempts to isolate poliomyelitis virus from the stools of typical (and borderline) cases of poliomyelitis, which occurred during 1943 among British and American troops stationed in the Middle East—particularly in Libya, Egypt, and Palestine. The tests have been undertaken to determine: (i) their local value as a confirmatory diagnostic procedure; and (ii) whether these adult cases (which have occurred for the most part sporadically) harbour the virus in the intestinal tract in the same manner as do juvenile cases in areas where the disease is more apt to be epidemic.

## Prevalence of Poliomyelitis in the Middle East

From the onset of this work we have been concerned with the circumstances under which this peculiarly severe type of poliomyelitis has occurred in civilian as well as military populations of the Middle East during recent years. In Egypt there is a dearth of published information on this point. Reports to the Egyptian Ministry of Health appear inadequate, for only a few cases—nearly all of them fatal—have been listed during recent years. Thus in the year 1938 the Egyptian Ministry of Health reported, for all of Egypt (16 million people), only 1 case of poliomyelitis, with 2 deaths; and in 1939, 8 cases and 8 deaths. To supplement this information we have obtained data from two prominent Cairo paediatricians,† who

TABLE I.—Incidence of Poliomyelitis at the Children's Hospital Dispensary, Cairo\*

Year	New Cases	Total New Patients Admitted to Dispensary	Approx. Rate per 1,000 Admissions
1933 .. ..	71	58,000	1.2
1934 .. ..	74	73,000	1.0
1935 .. ..	24	77,000	0.3
1936 .. ..	48	100,000	0.5
1937 .. ..	22	110,000	0.2
1938 .. ..	96	116,000	0.8
1939 .. ..	41	122,000	0.3
1940 .. ..	149	148,000	1.0
1941 .. ..	110	160,000	0.7
1942 .. ..	201	165,000	1.2

\* Data kindly furnished by Prof. Shawki.

agree that poliomyelitis is "not uncommon" in Egypt—a fact which becomes evident from a glance at Table I, which gives the number of new cases seen annually at the Children's Hospital Dispensary of Cairo.

\* From the Neurotropic Virus Disease Commission (Board for the investigation of Influenza and Other Epidemic Diseases in the Army, Preventive Medicine Service, Office of the Surgeon General, U.S. Army).

† We are indebted for this information to Dr. Ibrahim Shawki, Professor of Paediatrics, Faculty of Medicine, Cairo; and Dr. Edouard Debbas, Physician-in-Chief for Diseases of Children at the Israeli Hospital in Cairo.

Data in this table indicate a fairly high endemic rate for poliomyelitis in the civilian population of Cairo: probably it is greater than hitherto suspected. There have been fluctuations from year to year, but the disease has not appeared in epidemics during this period. Furthermore, in contradistinction to the experience in temperate climates, it is more of an all-year-round disease in Egypt, with maximal incidence in March, April, and May, and again in October.

Information about the civilian age groups involved is scanty, but most of the cases listed in Table I have been in patients under 5 years of age. Poliomyelitis in the native Egyptian adult seems to be rare, and from verbal accounts no cases have been seen recently at the Military General Hospital in Cairo. The local juvenile cases have usually been mild and severe bulbar cases rare. Prof. Shawki has seen only 2 cases of severe acutely ascending paralysis in local children.

In Palestine some information has been published by Levy (1937), who concluded that there, also, poliomyelitis was not uncommon, in that for the 20-year period 1915–34 he was able to collect from the records of orthopaedic dispensaries and physicians a series of 215 paralytic cases. From these data he estimated the average incidence of poliomyelitis to be only slightly lower than that of the United States! On the other hand, it was not common among the large native Arab population, the highest prevalence being among Jews (12.3 per 100,000)—an average rate 25 times that noted among Moslems. Seasonally, as in Egypt, there were two periods of increased incidence—one in May and June and another in October and November. And, again as in Egypt, the disease was largely one of infants—85% of the cases being recorded in children under 4 years of age. Adult cases were not mentioned.

This is the present setting in the Middle East, where many cases have occurred among British troops. To quote from van Rooyen and Morgan's report: In 1941 a total of 74 cases were notified as acute poliomyelitis or encephalitis in the M.E.F., and of these 19 were fatal; in 1942 there were 32 cases, with 14 deaths. The rate among American soldiers stationed in the Middle East (during the first 10 months of 1943) has been more than 10 times that recorded in the United States (see Table II) for a similar period of time.

TABLE II.—Poliomyelitis Rates per 1,000 in the U.S. Army

Year	In the Middle East	In the United States
1940 .. ..	—	0.02
1941 .. ..	—	0.02
1942 .. ..	7	0.03
1943 .. ..	0.425*	0.03†

\* To Oct. 1, 1943. † To Sept. 12, 1943.

## Clinical Epidemiology

Contacts and living quarters were investigated in 10 military cases of poliomyelitis or polio-encephalitis, which were probably acquired in Cairo between May 1 and Oct. 15, 1943. The cases were ubiquitous as to their place of origin. No two patients seemed to have been in contact. No civilian cases were discovered among adults or children living in close proximity to the patients' quarters. This does not mean that epidemics of poliomyelitis do not occur in the Middle East. Caughey has described, in an unpublished report, an epidemic of poliomyelitis which occurred in 1941 among New Zealand troops stationed in Egypt. Subsequently there have been other small localized outbreaks. During the summer of 1943 there were, two of these—in Libya and in Tripoli. We did not have the opportunity of examining these situations first-hand.

## Isolation of Virus from Stools

During the past five or six years methods of testing stools of poliomyelitis patients for virus have been revived by Trask *et al.* (1938) for purposes of diagnosis and epidemiological study. Recent published reports, of which there are many in American medical literature, now record positive isolation experiments in well over 100 cases. Advantages of testing stools rather than nasopharyngeal washings in this disease rest on the fact that in the average juvenile case the virus remains in the intestinal tract (during convalescence) for much longer periods (roughly 20 days) than it does in the nasopharynx.

(roughly 2 to 4 days). Most of the recent work by Trask *et al.* (1938 and 1940), Kramer *et al.* (1939), Howe and Bodian (1940), Kessel *et al.* (1941), and Sabin and Ward (1941a) in the United States; by Kling *et al.* (1939) in Sweden; and by Lépine *et al.* (1939) in France has been done on children, and it has been found to be easier to isolate virus from stools of young children (under 8 years old) than in children over this age. Information with regard to the presence of virus in the stools of adult poliomyelitis patients is far more limited.

Necropsy studies by Sabin and Ward (1941b) and by Kessel *et al.* (1941) in their series of fatal cases (most of which were in the second week of the disease) have also pointed to the intestinal tract as a site of predilection for the virus. They found that in this stage of the disease the virus was distributed predominantly in two systems: (a) certain regions of the nervous system; and (b) the walls of the pharynx and ileum, and the intestinal contents. These may not be the only locations at all times during the disease, but they are the most prominent after serious lesions have become established.

The epidemiological significance of the presence of poliomyelitis virus in the stools of human cases remains unsolved, for as yet the portal or routes of entry of the virus are unknown. Modern research has indicated that the nasal mucosa and olfactory bulbs can no longer be regarded as the main avenues of infection, because human necropsies have failed to reveal in these bulbs characteristic lesions which were shown to be present by Sabin and Ollitsky (1937) when the disease is induced experimentally in the monkey by instillation of virus into the nostrils. Indeed, if analogy existed between the human and the experimental disease, then it would seem that infection through the pharyngeal or gastro-intestinal tract should be seriously considered, because of the relative ease with which chimpanzees and cynomolgous monkeys may be infected by feeding them with virus.

Of further and possible epidemiological significance is the fact that the virus has been isolated from samples of sewage collected by Paul *et al.* (1940) in the United States, and by Kling (1940) in Sweden, during epidemics. Of more interest is the recent discovery of its presence in flies collected at different epidemic centres. This has been noted by Paul *et al.* (1941), by Sabin and Ward (1941c), and by Toomcy *et al.* (1941). Unfortunately, these findings do not indicate how the disease is disseminated, but they reopen the question whether poliomyelitis may not be legitimately placed among the excremental infective diseases pending such times as it may be proved otherwise. In fact, the evidence for other means of infection is appreciable, for poliomyelitis can be reproduced by injecting infective material *subcutaneously* in monkeys, as has also been the case in accidental human infections (Leake, 1935). Consequently, in view of this latter feature, one cannot ignore the possibility of the disease being transmitted by a biting insect. The need for intensive study on the widest possible scale is thus apparent.

#### Clinical Material

Stool specimens from 35 patients (and contacts) were tested; 17 of these were American and 18 British.\* Four different clinical types of case were chosen for study:

- (I) Fifteen typical cases of poliomyelitis were tested in all, of which 10 were fatal.
- (II) Five cases diagnosed *polio-encephalitis*, with a short (3- to 4-day) febrile course and paralysis limited to the cranial nerves. In several the epidemiological background and circumstances in which these cases were contracted were suggestive of poliomyelitis. Positive spinal-fluid findings consisted of pleocytosis varying from 30 to 60 cells (about 60% lymphocytes) and slightly increased protein content.
- (III) Six cases were diagnosed *acute benign lymphocytic meningitis*. Paralysis was not noted except in an occasional case in which there was a transient sixth-nerve lesion. The cell count in the spinal fluid ranged between 20 and 80 cells. In none of these patients did the fever last more than 4 days, and so for this and other reasons we have considered the diagnosis of lymphocytic choriomeningitis to be improbable.†

\* We are indebted in particular to Major C. R. Amies, R.A.M.C., for many of these specimens. Other members of the R.A.M.C. to whom we are indebted for the collection of specimens include Major H. K. Fidler, Lieut.-Col. J. H. Fisher, Major J. E. Caughey, and Major R. S. Illingworth.

(IV) Six cases in which localized *neuritis*, usually involving one or more limbs (generally the upper arms), has often followed a brief period of diarrhoea or fever, or both. A description of the syndrome as seen in New Zealand troops has recently been given by Burnard and Fox (1942). The spinal-fluid findings in our series have usually been normal.

(V) Three poliomyelitis contacts.

#### Laboratory Methods

Stool specimens were as a rule kept refrigerated (or preferably in the frozen state at  $-60$  to  $-70^{\circ}\text{C}$ . in a refrigeration box containing solid  $\text{CO}_2$ ) until ready to be tested. In most instances this period of preserving the sample before its inoculation did not exceed two weeks. Occasionally, when stool specimens were not readily obtainable, enema washings were substituted. In 7 instances colon contents were obtained at necropsy. The usual clinical course of these fatal cases was rapid, and by the second or third day constipation and profound prostration were such that in a large number of instances specimens of faeces could be obtained only at necropsy. In these circumstances a loop of colon was tied off with string, and the loop was excised and placed in the ice-box (for 24 to 36 hours) until the contents could be removed under sterile conditions.

In preparing faecal material for monkey inoculation the following procedure was used:

A 10% suspension in sterile distilled water (using at least 5 or 6 g. of solid or semi-solid stool) was prepared and allowed to settle at room temperature; the supernatant fluid, amounting to about 50 c.c.m., was then divided in half (parts A and B). Part A was kept at ice-box temperature and instilled into the nostrils (in 3-c.c.m. amounts) of a single monkey on three or four successive days; part B was immediately centrifuged for 20 minutes at about 2,000 r.p.m., and to the supernate 15% ether was added as a bactericidal agent. The etherized suspension was kept refrigerated for 48 or 72 hours and inoculated intra-abdominally in amounts of 15 to 20 c.c.m. into the same monkey. This concentration of ether was usually sufficient to destroy or diminish the number of bacteria in the suspension to proportions small enough to permit intra-abdominal injection of 15 or 20 c.c.m. of stool extract without fear of inducing peritonitis.

Daily rectal temperatures and exercise records were taken for a period of four weeks on all monkeys inoculated in this manner. A positive result was based on the following criteria in the inoculated animal:

1. "Clinical."—Signs of the experimental disease—viz., fever, tremor, weakness, paralysis, and prostration, all or some of which may be present in varying degrees.
2. "Pathological."—The presence of characteristic histopathological lesions in the medulla and various levels (cervical, dorsal, and lumbar) of the spinal cord.

With the exception of the experiments by van Rooyen and Morgan, who isolated poliomyelitis virus from the human spinal cord in grivet monkeys and baboons, the types of monkey used in these tests on faecal material have to our knowledge seldom before been employed in poliomyelitis work. Five different species were used: (i) grivet monkeys, *Cercopithecus griseoviridis*; (ii) Central African vervet monkeys, *Cercopithecus aethiops centralis*; (iii) small immature Abyssinian baboons, *Papio hamadryas*; (iv) Hussar monkeys, *Erythrocebus patas*; (v) the bonnet monkey, *Macacus radiata*.

Four of these species (Nos. i-iv), all from East Africa, were shown in these experiments to be susceptible to infection with poliomyelitis virus. Of these we have reason to believe that the baboons are the least susceptible by the various routes of inoculation used. The fifth variety, or bonnet monkey (from India), of which we had only three specimens, was not adequately tested. In the whole series of experiments (including passage experiments) 44 monkeys were used, 6 of the animals twice.

#### Results

A summary of the tests performed appears in Table III. In most instances the results have been listed according to the day of disease on which the stool was collected.

**Poliomyelitis Cases.**—Of the 15 cases tested, the stools (or colon contents) in 9 were positive for poliomyelitis virus.

† Likewise, in precisely similar cases, efforts to demonstrate specific neutralizing antibodies in the blood have all been unsuccessful.

JUNE 24, 1944

# POLIOMYELITIS IN TROOPS IN MIDDLE EAST

BRITISH  
MEDICAL JOURNAL

All of these positive cases proved to be fatal. In one of them the stool was obtained before the patient's death. In one of the 15 cases the result was unsatisfactory owing to the premature death of the monkey. These results suggest that

TABLE III.—Results of Stool Tests for Poliomyelitis Virus

Type of Case	Total Patients	Day of Disease Stool Collected	No. of Patients	No. Positive for Polio Virus	No. Negative	Locomotor Factory Tests
Poliomyelitis	15	3 10 4 18 5 20	9	6	3	0
Polio-encephalitis	1	4 2	1	0	1	0
Poliomyelitis contacts	1	4 2	1	0	1	0
"Benign lymphocytic meningitis"	1	4 2	1	0	1	0
Neuritis	1	4 2	1	0	1	0

\* The experiment was conducted developing poliomyelitis before the period of observation.

the amount of virus present in the intestinal tract was greater in the more severe than in the milder cases of poliomyelitis in this series—a finding which has not to our knowledge received comment before, and one which may not hold true in juvenile cases. Another point, however, in the interpretation of the high percentage of positive results from the faecal samples (which for the most part were fulminating in type) is that most of the "stools" were collected earlier in the disease (on the third to tenth day) than in the other poliomyelitis cases. It has long been recognized that the chances of obtaining positive results are greater during the first than during the later weeks of the disease.

Other Cases (Groups II, III and IV).—All tests for virus in the stools from cases other than typical poliomyelitis proved negative. Several of the monkeys developed fever without symptoms of myelitis and were killed. Histological examination of the spinal cord proved negative, and no doubtful positive results were obtained, but, needless to say, failure to find poliomyelitis virus in such cases does not necessarily exclude the disease.

## Summary

The stool test as a confirmatory means of diagnosis in clinical poliomyelitis has been used in 15 cases of typical poliomyelitis, 17 atypical cases, and 3 contacts, which occurred in British and American troops stationed in the Middle East during 1943.

From the 10 fatal cases of poliomyelitis the isolation of virus from stools was accomplished in 9 instances.

Negative findings have been encountered in the remaining 5 (non-fatal) cases of poliomyelitis (one test was unsatisfactory) and negative results were likewise encountered in 20 "atypical" cases (and contacts)—viz., 5 cases of polio-encephalitis, 6 cases of "acute benign lymphocytic meningitis," 6 cases of neuritis, and 3 poliomyelitis contacts. The negative virus findings do not wholly exclude the possibility of poliomyelitis.

Grivet and vervet monkeys, obtainable in East Africa, are highly susceptible to experimental infection with poliomyelitis virus.

This investigation has been aided by a grant from the National Foundation for Infantile Paralysis.

# SYMPATHECTOMY AND STERILITY

BY  
NORMAN C. LAKE, M.D., MS., D.Sc., F.R.C.S.  
Senior Surgeon, Charing Cross Hospital

A patient upon whom I performed a lumbar sympathectomy some years ago was recently on trial on a charge of "incest." His defence was that as the operation had rendered him sterile it was impossible that he could be the father of his daughter's child. This information he had culled from a surgeon whom he had consulted subsequent to the operation, but before the alleged crime was committed. As removal of part of the lumbar sympathetic chain is now performed with considerable frequency, and in view of possible legal implications, it is time that the question of any resultant sterility should, if our knowledge warrants it, be unequivocally settled.

The physiologists have a good deal to teach us regarding the mechanism of ejaculation and its dependence upon the autonomic supply to the base of the bladder. The course taken by the sympathetic supply is apparently a long one down through the so-called "lumbar splanchnics" and the pre-aortic plexus, coming particularly from the first lumbar contribution. As this part of the sympathetic fibres concerned with ejaculation should escape. But whatever the physiological and anatomical considerations, the practical outcome is whether in fact patients who have submitted to the operation can procreate and whether their semen is, normal.

It has proved more difficult than would be expected to get definite evidence to answer the first question. For reasons unconnected with physical sterility these patients appear very rarely to become parents after the operation. However, I know of two cases in which a child was born subsequent to the operation. The second question is more readily answered. I have examined several specimens of semen obtained from such patients which to my inexperienced eye appeared normal, but a more complete examination of some of the specimens has been carried out by Dr D. Embleton, to whom I should like to express my thanks. Sample results are as follows:

## Examination of Semen after Sympathectomy

- Case 1.—Aged 42; proximal type of thrombo-angiitis obliterans; one year after operation. Volume of seminal fluid, 1.5 c.cm.; pH, 8.0; colour, greyish white; number of spermatozoa, 212 millions per c.cm.; differential count, normal forms 54%, abnormal 46%; hanging drop, about 50% motile.  
 Case 2.—Aged 50; distal type of thrombo-angiitis obliterans; ten years after operation. Volume of seminal fluid, 1.5 c.cm.; colour, greyish white; number of spermatozoa, 162 millions per c.cm.; hanging drop, 83% motile.

This should be sufficient to convince the most sceptical jury in a criminal case.

## Comment

The thoroughness of the sympathectomy (which did not include the first lumbar ganglion) in all cases was, as usual, confirmed by microscopical study of the parts removed, as well as by the subsequent clinical history and sweating tests. This type of sympathetic denervation therefore produces neither sterility nor impotence, and so we can set at rest the minds of those who may hesitate to suggest lumbar sympathectomy, when otherwise advisable, on account of the fear of sterility. It remains a philosophical paradox that a mechanism as characteristically parasympathetic in its functioning as sexual intercourse should require powerful sympathetic activity for its consummation. Possibly the paradox really lies in our conception of an essential opposition in the action of the two systems, an idea encouraged by much physiological teaching.

A comprehensive statistical and epidemiological review of typhoid fever in Egypt from 1935 to 1942 was contributed by Dr. A. M. Kamel and Dr. G. A. Messih to the *Journal of the Egyptian Health Association* for December, 1943. A reprint of this review can be seen in the library of the B.M.A.

## A CASE OF MARCH HAEMOGLOBINURIA

BY

MYER MAKIN, M.B., M.R.C.S.

Captain, R.A.M.C.

March haemoglobinuria is a relatively uncommon condition characterized by the passage of free haemoglobin in the urine after marching or running. The condition was first described by Fleisher in 1881, and since then only 40 cases have been reported in the literature. All these have occurred in non-syphilitic males between the ages of 16 and 35 years. Because it is particularly likely to result from marching or running rather than other forms of exercise it tends to be found in armies more than in the civilian population. It attracted considerable attention in Germany in the last war, but so far very little in this country in the present war. The following case illustrates many of the characteristic features of the condition.

## Case History

Private D., aged 21, medical category A1, an infantryman, reported on March 24, 1943, that for the previous three weeks he had noticed a red discoloration of his urine on exertion. He stated that he had first observed that his urine was "dark brown" five months before, not after exercise but after having stood on guard. About two months previous to reporting sick he had been on some manoeuvres. The first two days were strenuous ones, but he noticed no "dark urine." However, on the third day, which was less strenuous, his urine was dark-coloured at mid-morning. Since then the same urinary abnormality has occurred after marching a few miles after running two to three hundred yards, and sometimes after playing football. He was naturally worried about his condition, but had not had any discomfort, pain, or other untoward symptoms.

There was no history of nephritis, venereal disease, or any other illness except measles in childhood. Both parents and two brothers were alive and well, and there was nothing relevant in their histories. On examination he was seen to be a sturdily built young man. There were no significant physical signs. Posture was normal and without evident lordosis. There was no icterus. The liver was not enlarged and the spleen not palpable. Blood pressure was 110/78.

**Investigation.**—This was carried out in his unit and at Catterick Military Hospital. He was sent out with an orderly on a half-mile run, specimens of urine being collected prior to and ten minutes after exertion. Urine examination revealed:

	Before Exertion	After Exertion
Appearance	Clear yellow	Dark brownish-red
S.G.	1032	1032
Albumin	Nil	Large amount
Sugar	Nil	Nil
Benzidine test	Negative	Very strongly positive
Spectroscope		Oxyhaemoglobin present
Deposit	Few epithelial cells. No red blood cells, pus cells, or casts	Many granular casts. Few epithelial cells. No red blood cells, pus cells, or casts

After a short rest urine examination revealed no abnormality. Blood investigation showed: Erythrocytes, 4,300,000 per c.mm.; leucocytes, 5,500 per c.mm.—polymorphonuclears 61%, lymphocytes 33%, monocytes 4%, eosinophils 2%; haemoglobin, 12.87 g. per 100 c.cm. (83%); C.I., 0.97; film, normal appearance; Donath-Landsteiner reaction, negative; erythrocyte fragility, normal (haemolysis began in 0.44% NaCl and was complete in 0.28% NaCl); W.R., negative.

The patient then had half an hour's strenuous exertion riding a pedal cycle. Urine examination of specimens collected showed:

Specimen	Albumin	Deposit
1 (resting)	Nil	Few epithelial cells.
2 (after 1 hour's cycling)	Trace	No red blood cells,
3 (after 1 hour's rest following 2)	Faint trace	pus cells, or casts
4 (after 2 hours' " " " 3)	Nil	

No blood pigments were present in any of these specimens. Benzidine reactions and spectroscopic examinations were negative.

As there was no evidence of renal damage the soldier was returned to full duty with his unit after hospital investigations. The only precaution taken was full dosage of sodium citrate before exertion in order to alkalize the urine. The haemoglobinuria following exertion gradually decreased until four months after first reporting sick it had disappeared. In September the patient was sent on a mile run, but there was no trace of haemoglobinuria from this

exertion. It is now reasonable to assume that spontaneous recovery has occurred. It is emphasized that, except for a period of two weeks in hospital, the patient has undertaken, without ill effects, all the rigorous duties demanded of an infantryman.

## Discussion

Because the condition may start suddenly without evident reason it is likely to prove alarming not only to the patient but to the medical officer. But the close association with certain forms of exercise and with nothing else should as a rule be sufficient to enable the diagnosis to be made. The finding of granular casts in the urinary deposit may lead to a misdiagnosis of nephritis, but these also are present only during the actual periods of haemoglobinuria, and are not indicative of renal damage. The dark brownish-red urine may be mistaken for haematuria and lead to extensive investigation of the renal tract for calculi, etc.; but in haematuria the centrifuged urine becomes clear, all red cells being carried down in the deposit, whereas in haemoglobinuria the pigment cannot be removed by centrifuging. Two other forms of haemoglobinuria are occasionally encountered. Paroxysmal haemoglobinuria may occur in syphilitics on exposure to cold. In this condition the Wassermann reaction is usually positive, and it is characterized by a positive Donath-Landsteiner reaction. In the other—nocturnal haemoglobinuria—the haemoglobinuria occurs characteristically at night and may be so severe as to cause a gross anaemia. In the great majority of cases it is possible to differentiate between these three forms of haemoglobinuria by careful attention to the history of the case.

March haemoglobinuria is usually caused by exercise taken in the upright position. It tends, like orthostatic albuminuria, to be associated with the lordotic posture, and sufferers may show no haemoglobinuria if made to undergo equally strenuous exercise in the kyphotic position. Gilligan and Blumgart (1941) were able to demonstrate this, and it was shown in the present case. It was noted also by Fisher and Bernstein (1940) that a marathon runner who developed this condition tended to assume an unusually lordotic position when running. In a case reported by Witts (1936), however, the haemoglobinuria could be evoked by exercise on a bicycle ergometer, and in the present case there was no evident abnormal degree of lordosis.

In spite of its alarming symptoms, march haemoglobinuria is a benign condition. It is unlikely to lead to serious anaemia; it does not seem to damage the kidneys; and it nearly always clears up spontaneously in a few months or at most a year or two. It is not due to syphilis, and its cause remains unknown.

## Summary

A case of march haemoglobinuria is reported.

The haemoglobinuria occurred only after exercise in the erect position.

The patient had no other symptoms and there was no interference with his efficiency as an infantryman.

Spontaneous recovery occurred.

I wish to thank Lieut.-Col. C. L. Cope, R.A.M.C., Officer i/c Medical Division, Catterick Military Hospital, for undertaking the hospital investigations and for his kind assistance in the preparation of the case report. I also wish to thank Col. J. C. McGrath, M.C. A.D.M.S., for permission to publish.

At the annual meeting of the Medical Insurance Agency held on May 31, with Sir Robert Hutchison, Bt., in the chair, Sir Kaye Le Fleming and Dr. Geoffrey Evans were elected to the committee of management for three years. Dr. J. W. Bone, Dame Barri Lambert, and Dr. Henry Robinson were re-elected for a like period. Distributions to the medical charities were authorized, mostly under seven-year covenants, by which they will benefit in the following amounts: Royal Medical Benevolent Fund, £2,958 12s. 4d.; Epsom College (including £50 for Sherman Bigg Fund), £889 13s. 2d.; Squire Sprigge Scholarship Fund, £58 7s. 2d. The report of the committee of management showed that, in spite of the steady diminution of motor insurance and of new life business, the net profit is still slightly above the pre-war average. Sir Robert Hutchison was re-elected chairman, and the proceedings were concluded with a vote of thanks, to him for services during the past year.

## Medical Memoranda

### Severe Tetanus with Recovery

The following case is of interest as an example of the efficacy of large doses of antitoxin given early in the treatment of tetanus, and emphasizes the need for wider knowledge of this method of combating the disease.

#### CASE HISTORY

A nursery foreman aged 65 lacerated the little finger of his right hand; he received no antitetanus serum, and the injury was treated at home with an ointment. Eight days after the accident he noticed stiffness of his jaw, and the next day this was followed by stiffness and pain in his back and neck. On the morning of the third day after the onset of symptoms he received 1,000 units of antitetanus serum intramuscularly and was sent to hospital.

On admission all the physical signs of tetanus were present except spasms. He received 30,000 units of A.T.S. intravenously soon after arrival, and three hours later 50,000 units by the same route and 40,000 units intramuscularly, followed by 60,000 units intramuscularly the next morning; the total dosage was thus 211,000 units in 24 hours. He was given 40 gr. of chloral hydrate by mouth; and his finger was dressed with hydrogen peroxide at frequent intervals. The following day he was opisthotonic, perspiration was profuse, and several spasms occurred mainly involving the muscles of the back. He was given 6 drachms of paraldehyde in oil per rectum. For the next 18 days he had 3.4 g. (0.06 g. per kilo) of tribromethyl alcohol (avertin) per rectum night and morning, making a total of 118 g. He was sufficiently conscious before each administration to allow oral feeding, and deglutition was at all times possible. He received about 2,000 calories a day. Although his fluid intake was 60 fl. oz. and his urine output 30 fl. oz. a day he was becoming dehydrated by sweating, and on the seventh day of the disease he was given intravenously 2 pints of 5% dextrose in normal saline. From the eighth day onwards he improved daily, and on the thirteenth day he could open his mouth more readily. Avertin was discontinued on the twenty-first day; he had three doses of 30 gr. of chloral hydrate on the next two days, after which sedation was discontinued. He got up for the first time one month after admission and was discharged a week later. His temperature rose to 99.4° F. on the twentieth and twenty-first days of the disease, but was otherwise normal.

#### COMMENT

The successful recovery of this case in spite of the onset of the disease eight days after injury, the onset of spasms only four days later, and the age of the patient, serve to emphasize the effectiveness of early administration of massive doses of antitoxin in the treatment of tetanus, and also to show that intrathecal injection and further administration are unnecessary. Too much stress cannot be laid on the importance of adequate sedation and at the same time the maintenance of sufficient nutrition and fluid intake.

PETER H. SCHURR, M.B., B.Chir.,  
Resident Surgical Officer.

Worthing Hospital

### Seven-year Cure in a Case of Carcinoma of the Bronchus

Apart from those cases in which early recognition may in suitable conditions render lobectomy with removal of the growth possible, the prognosis is hopeless whatever method of treatment is adopted, and a cure is rare. The following case is of interest in that non-radical treatment has produced a complete cure for the last 7 years.

#### CASE HISTORY

The patient, aged 53, a carver and gilder, was admitted to the Middlesex Hospital for the first time on March 19, 1937, complaining of a heavy feeling in the chest, with dyspnoea, for the previous 4 weeks; burning pain in the right scapula on coughing, for the last 7 days; long-standing harsh dry winter cough, worse recently, with scanty non-offensive sputum. He had lost 2 stone, and weighed 8 st. 12 lb. There were occasional palpitations, no haemoptyses or sweats, and no anorexia.

Clinical examination revealed poor nutrition, with septic teeth, but normal mucosae. No clubbing of fingers, cyanosis, oedema, or glandular enlargement could be demonstrated. Pulse, 100 regular; respirations, 20-26; B.P. 130/80. No enlarged veins were seen, and the trachea was central. Most physical signs were found over the right chest: diminished excursion; impaired percussion note at lower and mid-zones posteriorly and laterally, with absent breath sounds; weak breath sounds, bronchial in character, and crepitations towards the apex. Compensatory harsh vesicular breathing was present over the left chest. No abnormality was detected in the heart or C.N.S.

Investigations and Treatment.—Screening and x rays showed normal movement of the diaphragm, also an opacity in the right mid-zone which was posterior in position: coelocclusions? early collapse. Lipiodol was found not to enter that area. The Wassermann reaction was negative. Bronchoscopy was performed by Mr. C. P. Wilson on April 6, 1937. A growth was found obstructing the dorsal division of the right lower lobe bronchus, and a portion was removed for microscopy. This showed infiltration of

tissue by squamous-cell carcinoma. Ten days later bronchoscopy was repeated as before, and 9 × 1.6 mc. of radon in short Muir seeds were inserted round the site of the growth. The patient was apyrexial throughout. The erythrocyte sedimentation rate on admission was 6.6 mm./hour; one week before bronchoscopy it was 7.8 mm./hour, the day after bronchoscopy 8.2 mm./hour, and one week later 7.6 mm./hour. Convalescence was uneventful and he was discharged one month after admission. No post-operative irradiation was given.

A regular follow-up was maintained. Three months after discharge his weight was 9 st. 1 lb.; he was feeling much better and had only a slight cough. The pain had entirely disappeared, as had the dyspnoea. Radiographs showed the radon seeds still *in situ*. Since that time he has had frequent x-ray examination at 3 to 6 months' intervals. The previous opacity in the lung field disappeared, and no further change occurred in his physical state.

Readmission.—The patient was readmitted on Nov. 22, 1943, with gradually increasing symptoms of seven weeks' duration: cough and colourless sputum; moderate dyspnoea; pain in right chest radiating to the back. His weight was now 8 st. 7 lb. On examination there was weaker air entry, with a few rales on the right side, together with harsh vesicular breath sounds on the opposite side. Nothing else relevant was observed. Radiographs of the chest showed no evidence of lung collapse. Three seeds were still present in the main bronchus and one lower down. Hb. 102%; W.B.C. 5,700; E.S.R., 25 mm./hour Westergren. Sputum: No malignant or tubercle bacilli seen; numerous organisms were present, the pneumococcus being predominant. Bronchoscopy was performed by Dr. J. E. G. Pearson under local cocaine anaesthesia and pentothal. Slight general constriction of the right lower lobe bronchus was found at the level of the middle-lobe opening. The area surrounding the dorsal lobe appeared somewhat pale—? fibrotic; the lumen of this branch seemed grossly constricted, and had been presumably the seat of the neoplasm as indicated by the original notes and diagrams. A portion of this area was taken, and microscopy revealed only respiratory epithelium, mucous glands, smooth muscle, fibrous tissue, and cartilage; no evidence of growth. The patient improved greatly with conservative treatment. He was discharged 34 weeks after admission, and is now back at work in an aircraft factory.

#### COMMENT

The effects of treatment of carcinoma of the lung were recently estimated by the Clinical Cancer Research Committee (British Empire Cancer Campaign Annual Report, 1943), who showed that radium application, although used in fewer cases, appeared to yield better results than x-ray treatment, the expectation of life being increased by 13 to 22% as against 6% in the latter.

I am most grateful to Dr. C. E. Lakin, Mr. C. P. Wilson, and Dr. J. E. G. Pearson for their permission to publish this case.

DAVID A. FERMONT, M.R.C.S.,  
House-physician, Mount Vernon Hospital, Middlesex.

### Post-mortem Appearances of Malignant Tertian Parasites

In the description of a fatal cerebral case of malignant tertian malaria given in the *Journal* (1943, 2, 814) difficulty was encountered in finding malaria parasites in sections of brain and spleen. Although textbooks stress the importance of making films at the time of post-mortem examination in order to detect parasites in the viscera, the following short account of the actual appearance of films from brain and spleen in such a case may be of use:

**Films from Brain.**—Thin smears from cerebral cortex are made in the post-mortem room. These are fixed and stained by Leishman's method. Chains of parasites are seen occluding the cerebral capillaries. The parasites stain blue, and each contains a dark mass of pigment. The course of the cerebral capillaries is in fact made strikingly clear by these characteristic chains of pigment-containing parasites. The red cells in which the parasites are contained are not readily distinguishable, however. Most of the parasites appear to be schizonts, and differential nuclear staining and division into merozoites can be seen in the thinner parts of the film.

**Films from Spleen.**—In spleen smears, similarly prepared and stained, the minute structure of the enormous number of sporulating schizonts is readily distinguished. Only some of the parasites, however, can definitely be located within red blood cells. The cytoplasm of the parasites is stained slaty blue, and the chromatin of the nuclei gives a beautiful metachromatic violet-red reaction. All stages in schizogony are encountered from early nuclear division to final liberation and separation of the individual merozoites, which can be seen migrating freely in the splenic pulp. Many of the merozoites are in "rosette" arrangement, grouped in the merozoite, and each merozoite is clearly seen to contain a violet-red chromatin particle and a slaty-blue cytoplasmic mass. The pigment of each merozoite is generally prominent as a brown-black concretion, often centrally situated. As many as 20 merozoites can easily be counted as emanating from some of the merozoites.

The above description illustrates the appearance of parasites of *Plasmodium falciparum*, which may readily be observed in films from spleen and brain within half an hour of completing post-mortem examination on a fatal pernicious cerebral case. The advantage of making films over sections in such cases is thus evident.

## Reviews

### MENTAL HEALTH IN OLD AGE

*New Goals for Old Age.* Edited by George Lawton. (Pp. 210. 22s.) New York: Columbia University Press; London: Oxford University Press. 1943.

"Everybody wants to live long," said Talleyrand, "but nobody wants to be old." Recently it has been forced upon public attention that the proportion of the old to the young is rapidly increasing, a change which creates problems of its own. On the whole, the medical profession have not been greatly interested in these, despite the writings of Sir George Humphry and Sir Humphry Rolleston on the subject. A non-medical book by Cowper Powys entitled *The Art of Growing Old* is a notable illustration of how not to do it. The book before us, which is of more serious import, is a collection of lectures delivered by different authorities in a course on "Mental Health in Old Age" in New York, and suffers somewhat from the lack of unity inherent in this method. Yet the result is helpful if rather diffuse. Emphasis is rightly laid on the importance of thinking during middle life of what later life may have in store and of making adaptations accordingly. To pass from full occupation on a fixed date to complete inactivity is fraught with danger, as Elia found, "thinking I was happy, and knowing I was not. I was in the condition of a prisoner in the old Bastille suddenly let loose . . . I missed my old chains." As the editor of this volume puts it, "It is fear of ageing rather than the ageing process itself which often causes a fundamental loss in the mental realm, just as it does in the physical. Anticipating the loss of efficiency, we hasten the arrival of what we expect." The acceleration in the rate of social change imposes a strain on the old, for it renders the private worlds they have built up years ago increasingly incompatible with the external one. How the individual handled life in the past is the best clue to whether he is equipped to face the problems of advancing age. In a curious way the temperamental make-up of childhood, whether conducive to happiness or unhappiness, may reappear. It is well known that senescence has no fixed date, and heredity is undoubtedly the most important factor. Interesting instances are related here of identical twins, living under different conditions, ageing in precisely the same way at the same time. The date of senescence therefore appears to be inherent in the germ plasm.

"In the years to come we shall have to develop a whole repertory of ways to utilize the judgment and experience of older people, whether these be in an advisory or teaching capacity," for "the older individual retains almost unimpaired his capacity for solving mental problems of equal difficulty to those he could solve when younger." Though originality will decline, discrimination may increase. The field of interest is apt to contract, and the most subtle temptation for the old person is to excuse himself for yielding to such contraction on the score of age. For those unable to find interesting occupation for themselves schemes of occupational therapy are described which are in actual operation. An important section of the book is devoted to the subject of institutional homes of various grades, where some sort of community life can be enjoyed. Such are already in existence in this country also, as organized by Mrs. A. V. Hill and others, but the future will call for far more. In short, as the writers maintain, old age must be made to feel that it still has usefulness if it is to be "frosty yet kindly."

### CONDITIONS OF MEDICAL WORK

*An Industry of Health. Being an Exposition of Assumption B.* By T. B. Layton. M.S., F.R.C.S. (Pp. 96. 3s. 6d.) London: William Heinemann. 1944.

The advertisement on the back of this book says that it is intended to "give the layman a background which will assist him to understand, assess, and criticize the proposals so that his views may be heard and his needs fully considered and met." Mr. T. B. Layton approaches his subject, which has a direct bearing on the White Paper proposals, in a novel way by drawing an analogy between medicine and ordinary industry.

The latter has evolved from the solitary handicraftsman to the organized factory, and medicine is following the same course. Domiciliary treatment has lagged behind, and Mr. Layton says it can "no longer remain in the primitive condition where the individual does everything." The team work characteristic of a good hospital must be provided for, and the key position of the doctor giving domiciliary treatment is fully recognized.

He divides the doctors into clinicians and others, and these others into two classes: "one which produces the evidence for the clinician which he is unable to obtain himself with his six senses," and the other the laboratory worker and the administrator. Some acute comments are made on the place of the administrator which are relevant to the discussion of the White Paper. Mr. Layton insists that no clinical interference from the administrator should be allowed, and he thinks that "a want of clear distinction between clinical interference and clinical administration is the chief cause of the alarm that at present exists in the profession."

The chapters deal with every branch of medicine, including the various sections of the medical profession, ranging from the pharmacist, nurse, and dentist, to the almoner and receptionist. Of the nurse, he thinks that "for the rank and file of the nursing profession we should not ask for any standard of general education higher than that at which we aim for all. Girls from humbler homes make better nurses than those from the well-to-do. They have had experience in these fundamentals since infancy." He gives two chapters to the discussion of health centres, in which he strongly supports the need for experimentation. He believes there is room for both the State and the voluntary hospital. In the State hospitals the chief defects, he thinks, arise from the methods of control, on which subject he is very critical.

It is to be hoped that the book will be widely read, not only by the laymen for whom it is primarily intended, but also by those members of the profession who are anxious to consider every point of view in this important discussion, whether it comes from the idealist or from those who know by experience what they are talking about—as Mr. Layton does. He has had a long experience in both kinds of hospitals, and has taken an active part in National Health Insurance administrative work.

### YEARBOOK OF SURGERY

*The 1943 Year Book of General Surgery.* Edited by Ewart A. Graham. M.D. (Pp. 736; illustrated. \$6.00 or 19s.) Chicago: The Year Book Publishers, Inc.; London: H. K. Lewis.

The distinguished editor of this book comments on the retardation that war inflicts upon scientific progress, and suggests that the volume for 1943 may appear to be less rich in new ideas than previous ones. This is questionable, however, for this year's survey strikes us as containing much that is new and important, and we must not lose sight of the fact that, while no doubt much is lost to surgical progress by war, much is also gained, particularly in the field of traumatic surgery. Wars have brought about advances in wound treatment from Ambrose Paré's time onwards, and we might remark that the sulphonamides and penicillin have quickly come into their own in the present carnage. It is conceivable that in times of peace their general adoption might have been a much slower process. We should have liked to see more about penicillin in the present volume—there is only one brief reference to it as a prophylactic against gas gangrene. No doubt next year's survey will remedy this defect, however, and give us a comprehensive account of the results of its employment in the treatment of wounds and infections generally. With the exception of urology, gynaecology, and some parts of orthopaedics, recent contributions to all branches of surgery are reviewed. There are in this issue, perhaps, fewer of those small-print, pithy, and pleasing editorial comments than usual, but last year's innovation of what is called a "surgical practice quiz" is continued on the dust cover; it is a series of questions relating to recent developments, the answers to which are to be found in the text.

This is an important publication, to the appearance of which we always look forward. There are some excellent papers reviewed in the present issue which no busy surgeon can afford to neglect.

# ANACARDONE

TRADE MARK

(NIKETHAMIDE B.P.)

Anacardone is the cardio-vascular and respiratory stimulant for routine emergency use.

It is administered by injection in all states of severe shock and collapse; in mild cases it is administered orally.

Anacardone is issued as follows :

Solution for injection (Inj. Nikethamid. B.P.)

2 c.c. Ampoules — Boxes of 6, 12, 25 and 100

5 c.c. Ampoules — Boxes of 3 and 12

Solution for oral use (25 per cent., with flavouring)

Bottles of 15 c.c. and 100 c.c.

*Details of dosage and other relevant information will be gladly supplied on request.*

## Insulin A.B.

Over 20 years ago Allen & Hanburys Ltd. and The British Drug Houses Ltd. decided to pool their resources in regard to the manufacture of Insulin. The object was to make available as quickly as possible, a supply of Insulin in this country.

Insulin A.B. was the result.

It was one of the first British Insulins to be offered commercially to the medical profession and was sold in 5 c.c. vials (20 units per c.c.) at 25/- per vial. Through constant research and improvement in the manufacturing process, the same high quality and quantity of Insulin A.B. is now sold at 1/3. Insulin A.B. conforms to every test and combines the high reputations of two famous British manufacturing houses.

## THE GROWING DANGER

During these crucial years of war, the increasing incidence of venereal disease has been recognised as a deadly menace to the world of tomorrow.

Many times before in the world's history medicine has had to challenge this insidious enemy—but never with such prospects of success as today. Through years of painstaking research and endeavour, science has evolved weapons more efficient, more dependable than ever before. The production of these weapons—arsphenamines, bismuth preparations and diagnostic products of the highest degree of purity and reliability—is part of the Burroughs Wellcome & Co. contribution to a healthier world.

# 'ROCHE' News in Brief

## Prevention of Muscular Fatigue

A report refers to 223 persons who were divided into two groups. The first group of 25 subjects was put on large doses of ascorbic acid ('Redoxon'), viz., 150-350 mg. daily, for several days before engaging in strenuous physical exertion such as riding, mountaineering, heavy work in gardens or fields. Only one person complained of muscular fatigue (4%). Of the controls, 198 subjects, undergoing the same exertions, 162 experienced severe muscular pain (80.8%). To protect against muscular fatigue amounts far above the anti-scorbutic doses are required. (*Rev. Med. Suisse Rom.*, 1943, No. 8, p. 640.)

## Ocular Signs of Riboflavin Deficiency

In a recent paper (*Lancet*, 1944, 1, 431) it was pointed out that a group of cases exhibited corneal vascularisation of a particular recognisable type which rapidly diminishes when riboflavin is given in sufficient doses. This condition was found in 7.8 per cent. of 422 persons. The effect of riboflavin was studied in 13 cases for an adequate period, and it was found that it produced cessation of the abnormal corneal circulation. Small doses of riboflavin (3 mg. daily) caused only slow improvement, but 10 mg. daily led to much more rapid diminution, usually complete in 3-4 weeks.

## Stomatitis due to Riboflavin Deficiency

In a camp in North Africa containing 10,313 men of many races, nearly 17 per cent. was observed to have stomatitis. On a diet containing an average of 1.61 mg. riboflavin per day the camp population had been free from stomatitis. It developed about two months after the daily riboflavin intake was reduced to about 1 mg. per head, and it was not abolished by the intake of 1.28 mg. in the following month. The stomatitis yielded rapidly to treatment either with riboflavin (100 mg. in five days) or fresh yeast (½ oz. daily). The lesions on the tongue were studied with a slit lamp. So far as the authors of the paper know this has not been done before, and they add that the method is useful and might be exploited further. (*Lancet*, 1944, 1, 720.)

## 'Prostigmin' in Glaucoma

Thirty-one patients suffering from glaucoma were treated with 'Prostigmin' with good results, the drug producing the desired fall in intraocular pressure. In the majority of cases a 3 per cent. solution was given; in rare cases 5 per cent. was given when there was a great increase of tension. In certain cases the concentration was reduced to 1 per cent. after the tension had been brought to normal with a 3 per cent. solution. (*Ophthalmologica*, 1942, 104, No. 1.)

A special 3 per cent. solution is now available for the treatment of glaucoma. The retail price in the United Kingdom of this preparation is 10s. per 7.5 c.c. in dropper bottles.

# 'Allonal'

## RELIEVE PAIN

*Controls fear and counteracts  
toxic effects of local anaesthetics*

Each 'Allonal' tablet contains allyl-isopropyl-barbiturate of amidopyrine 0.126 gm. (approx. gr. 2), amidopyrine B.P. 0.034 gm. (approx. gr. ½). Issued in bottles of 12, 100 and 500.

## X-RAY DIAGNOSIS OF JOINT DISEASE

*The Arthropathies. A Handbook of Roentgen Diagnosis.* By Alfred A. de Lorimer, M.A., M.D. (Pp. 319; illustrated, 35.50.) Chicago. The Year Book Publishers, Inc.; London: H K Lewis

This is one of a series of six handbooks dealing with the various branches of x-ray diagnosis. The foreword stresses the importance of the radiographer being given the opportunity of studying the clinical and laboratory data in order to arrive at a correct interpretation of the x-ray findings, and if this were the universal practice it would add greatly to their value. Following out this practice the author has described the pathological appearances at different stages of the various pathological conditions dealt with, and follows this with an account of the age and sex incidence, the history, physical and laboratory findings, and the clinical course. By this means he furnishes a picture of the disease, concise and yet complete to a remarkable degree, which cannot fail to be of great value not only to the student of roentgenology but also to the general practitioner. Every conceivable disease of the joints appears to have been dealt with in a thorough manner, and illustrated lavishly, as may be judged from the fact that the number of figures—mainly reproductions of radiographs but with some anatomical diagrams—amounts to 678. The importance of studying the appearance of the soft tissues as well as the bony structures receives prominence, and a very useful feature is the separation of the likely changes from those which may only possibly be present.

The illustrations are on the whole good and clear, the matter is compactly arranged, and supplies a mass of information in a remarkably small space and at a very reasonable cost. The book is one that can be strongly recommended to all who are concerned with the diagnosis of bone and joint diseases, and will be found a most useful addition to the library of the general practitioner.

## Notes on Books

As the editors of the new edition of *Textbook of Medical Treatment* (E. and S. Livingstone; 30s.) truly remark, it is a striking commentary on the rapidity of advance in medical therapeutics that the publication of its third edition only two years after the second should involve extensive changes in the text. The difficulty of keeping such works up to date and the inevitable delays in publication are illustrated by the absence of penicillin from the index. Among the sections that have been completely or partly rewritten are those on cerebrospinal fever, sprue, haemorrhagic and haemolytic diseases, blood transfusion, diabetes insipidus (where pitressin tannate has proved a real advance), parathyroid tetany (where vitamin D or dihydrotachysterol has been shown to be so superior to parathormone therapy that it might well be abandoned), and essential hypertension, of which it is justly said that its complications are more devastating than those of malignant disease. As might be expected, considerable emphasis is laid on peptic ulcer, now so prevalent, and on tuberculosis, now on the increase. The invasion of the surgeon into the chest continues with benefit. There is evidence throughout of careful revision, and we can cordially repeat the welcome we extended to the earlier editions. Particularly do we appreciate the explicitness of the directions given and the avoidance of vague and ambiguous statements, which greatly enhance the value of this excellent work.

*The Year Book of General Therapeutics, 1943* (Year Book Publishers of Chicago and H. K. Lewis; 19s.) aims at collecting in one handy volume information on diagnosis and treatment published during the year. The editor is to be congratulated on the result, for the book is readable and informative despite the wide range of subjects. The matter is essentially a series of abstracts, but as those relating to one subject are collected together, and are written with much fuller explanation than abstracts usually are, they provide an interesting text. There is a long chapter on the sulphonamides, and another, on penicillin. Matters dealt with prominently are the treatment of burns, malaria and syphilis, blood transfusion, blood diseases, hormones and vitamins. The book offers a solution to the doctor's problem of keeping up with new work, and, provided that as years go by it retains its present convenient size, it is likely to have a steadily expanding sale.

Mr. H. J. B. ATKINS's book *After-Treatment*, a guide to general practitioners, house officers, ward sisters, and dressers in the care of patients after operations, was favourably noticed in these columns on July 25, 1942. A second edition has now appeared (Oxford: Blackwell Scientific Publications; 18s.). There are two new chapters, one on post-operative treatment of children and another on rehabilitation. There are also new sections on post-operative coronary

thrombosis and on the management of the diabetic patient in the post-operative period. The section on head injuries has been brought up to date and now incorporates much of the teaching of the Oxford school. The book in its revised form should be very welcome at the present time.

## Preparations and Appliances

## AN IMPROVED SACCHAROMETER

Dr. J. E. STANLEY LEE, F.R.F.P.S., F.R.C.S.Ed., medical superintendent, New Cross Hospital, Wolverhampton, writes:

An apparatus for the rapid estimation of sugar in urine by Fehling's method using a modified Bink's burette was described by Carwardine,<sup>1</sup> but the graduations showing the amounts of urine and water to be added are not clearly indicated, with the result that inaccurate findings are obtained and the use of Fehling's method makes it extremely difficult to ascertain the exact end-point.

In order to overcome these difficulties, an improved model has been devised and adapted for use with Gerrard's cyanocupric method, which depends upon the fact that the colourless double cyanide of potash and copper is capable of holding cuprous oxide in solution. If, therefore, Fehling's solution is titrated with a sugar solution in the presence of this cyanide, the blue colour fades gradually, no precipitate being thrown down. The colourless end-point is thus very sharp, and, as there is no tendency to re-oxidation, the process may be safely conducted in an open flask.

The saccharometer tube, which has a double scale (c.c.m. on the left and sugar percentages on the right), is so graduated that the urine is diluted to 1 in 10; the formula being:

$$\frac{\text{c.c.m. diluted urine used}}{25} = \frac{1}{10} \text{ sugar in specimen.}$$

No cork is necessary with the present apparatus because the lumen of the nozzle has been adjusted to a convenient size, and an Erlenmeyer flask with a long holder has been chosen with a view to reducing the risk of accidents due to escape of the boiling solution.

## Directions

1. Fill measure to mark "GW" with Fehling-Gerrard's solution (Fehling's solution 1 part, Gerrard's solution 3 parts).
2. Pour into flask (or large test-tube).
3. Fill burette to "U" with urine, dilute by adding water to "DU," place finger over opening and mix well by inverting the burette.

## Estimation

1. Boil flask (or large test-tube), add, whilst boiling gently, add diluted urine from the burette until the blue colour is discharged.
  2. Hold burette vertically and read off percentage of sugar.
- When the quantity of sugar in the urine is very small, the burette can be filled with undiluted urine to the mark "DU," when the percentage obtained should be divided by 10.

A mixture of Fehling's solution 1 part and double cyanide 3 parts will keep for a number of weeks<sup>2</sup> and can be obtained from British Drug Houses, Ltd. Provision has also been made for estimation by Fehling's method, the measure being graduated for Fehling's solution Nos. 1 and 2, and for dilution to mark "GW" by water instead of Gerrard's solution.

I wish to thank Messrs. Down Bros., Ltd., who have made the apparatus for me and also provided the necessary electro for the illustration, and Mr. A. W. Farmer, laboratory technician, New Cross Hospital, Wolverhampton, for his technical assistance.

## ARTIFICIAL RESPIRATION

Though artificial respiration is a universally employed treatment that often proves life-saving, its investigation has been somewhat neglected in the past; but interest in the subject has been renewed in recent years, as exemplified by the important work of Hemingway and Neil reported in our opening pages this week. Yandall Henderson used to say that in America many laymen, such as ambulance personnel, members of the police force, and workers in high-tension plants, were often better trained to carry out artificial respiration than were some doctors; in fact, in one great American city the public were advised when faced with a case of asphyxia to ring up the fire brigade first and the doctor second. Without accepting Henderson's criticisms of our American colleagues we can say that British doctors nowadays are fully alive to the importance of being thoroughly familiar with artificial-respiration technique. But there still remains much doubt as to which is the best method to employ, and, in fact, there is uncertainty about the criteria by which any method of artificial respiration should be judged.

A sharp distinction must be drawn between the problems involved in treating a case of gradually progressive respiratory paralysis (like that complicating anterior poliomyelitis) and those of acute respiratory failure due, for example, to drowning, inhalation of irrespirable or poisonous gases, suicidal and accidental overdoses of narcotics, and electrocution. In the chronic group there is usually ample time to use a breathing-machine. In the acute group not a moment may be lost, and the treatment must be capable of being carried out by the first instructed person on the scene and require the use of no more equipment than can be readily improvised almost anywhere. There is another fundamental difference—which is often overlooked—between the chronic and acute forms of respiratory failure. In the former machine-breathing is instituted while the circulation is functioning normally; if the mechanical respiration is efficient no circulatory derangement develops and the blood-flow to all the organs remains normal. In acute asphyxia, on the other hand, failure of the circulation and of the central nervous system follows rapidly in the train of respiratory arrest. The body is unfortunately quite unadapted for dealing with complete or even very severe oxygen lack. Food starvation can be withstood for weeks and water deprivation for a few days; but grave anoxia "stops the machine and wrecks the machinery" (to use J. S. Haldane's unforgettable phrase) in a matter of minutes. Let us consider the sequence of events in drowning, for example. After one minute or so of complete lack of oxygen consciousness is lost; within another minute or two the respiratory centre, which initially was stimulated, ceases to function. The

vasomotor centre is more resistant and may maintain vasoconstriction for a little longer, but soon it too fails, and full peripheral vasodilatation sets in, with a resulting fall of blood pressure to about 40 mm. Hg. Most important of all, we must always remember that the heart—unlike skeletal or smooth muscle—can function normally for only a short time in the absence of oxygen; it has no type of anaerobic metabolism to fall back on. The force of the heart-beat in severe anoxia rapidly weakens and the chambers greatly dilate; the output into the blood vessels is reduced to a trickle, and the blood-flow to the organs almost ceases. When fibrillation of the ventricles develops the chances of recovery are of the slenderest. Acute asphyxia thus presents a combination of respiratory, circulatory, and nervous-system failure with which the treatment employed must cope effectively if it is to succeed.

There is no disagreement as to the immediate action which should be taken. As Hemingway and Neil emphasize, "the Schäfer method should be immediately instituted when resuscitation is undertaken," and "no time should be lost while preparations are being made for the use of any other method." Incidentally, it should be made clear to laymen that in the Schäfer method pressure is not applied over the lower part of the chest but over the lumbar region; compression of the abdomen so brought about drives its contents on to the diaphragm, which diminishes the size of the thoracic cavity and causes expulsion of air from the lungs. The active phase is thus expiration. When pressure on the loins is released the diaphragm descends once more and air is drawn into the chest. In normal subjects who have voluntarily suspended their respiration it is easy to demonstrate that Schäfer's method produces an adequate pulmonary ventilation; but it has been argued that some degree of active co-operation is being supplied by the conscious subject. To avoid this complication experiments have been performed during the apnoea which follows a bout of vigorous over-ventilation. Under these conditions a disappointing degree of lung ventilation is obtained, which is said to contrast poorly with that yielded by the Silvester method. But in over-ventilation apnoea there may be a good deal of muscular rigidity which constitutes a mechanical hindrance. Ideally to test artificial-respiration methods, observations should be made on the fresh, warm, non-rigid cadaver or on cases of respiratory failure from overdosage with anaesthetics or narcotics; but as yet data from such sources are very scanty. It has been argued theoretically against the Schäfer method that in unconscious subjects muscle tone is lost, that consequently the diaphragm will not recoil (as normally) into the abdomen when pressure is removed from the loins, and that effective inspiration will therefore not be produced.

The chief competitor of the Schäfer method in this country is the rocking method introduced and persuasively advocated by F. C. Eve. It only requires some kind of stretcher and fulcrum; it is easily and conveniently carried out aboard ship. The principle of the method is straightforward enough. When the head is tilted down the abdominal viscera fall on to the diaphragm and compress the contents of the chest, producing expiration; with the feet down the viscera pull the diaphragm back into the

abdomen; the thoracic cavity is enlarged, and inspiration results. It is claimed that even the toneless diaphragm responds adequately to these mechanical forces. Hemmingsway and Neil have compared the efficiency of the Schäfer and rocking methods in dogs in which respiration was abolished by deep anaesthesia or section of the upper cervical spinal cord: in both groups muscle tone, including that of the diaphragm, was practically absent (as is the case in asphyxiated human subjects). The volume of the tidal air was found to be generally smaller with the Schäfer method, the mean advantage in favour of the rocking method being 50% and most pronounced when the loss of muscle tone was most complete. These results lend substance to the criticism of the Schäfer method already referred to.

But it must be remembered that resuscitation demands more than just effective pulmonary ventilation: the oxygen introduced into the lungs must be transported by the circulation, especially to the brain, heart, and kidneys. As only a minimal circulation is present in asphyxiated patients, and life is being maintained most precariously, quite small differences in the circulatory state produced by the resuscitation technique may be of decisive importance. Hemmingsway and Neil have shown clearly that even with equal degrees of pulmonary ventilation the rocking method is associated with a greater cardiac output and therefore with a better blood-flow to the organs, and with a higher level of oxygen consumption. These important advantages of the rocking method are largely due to obvious mechanical factors. In the head-down phase the venous blood drains out of the legs and abdomen into the heart, and the arterial blood-flow into the head is facilitated. During the feet-down position venous blood drains out of the head, and the lower part of the body is fed with arterial blood, though the venous outflow from that region is impeded. Some of these advantages are lacking in the Schäfer method. A good case has been made out experimentally for changing over from the Schäfer to the rocking method as soon as suitable facilities are available. It seems that an angle of rock of 45° is adequate; employing a rate of 8 to 9 rocks per minute, the 7-second cycle might be divided into 4 seconds head down and 3 seconds feet down to obtain the full circulatory benefits of the head-down position. It is to be hoped that the circulatory changes during resuscitation in man will receive more careful consideration in the future.

### THE WAY OF THE INVESTIGATOR

"Every physiologist who is more than a technician is something of a philosopher because he is constantly dealing with the problem of life, and sooner or later he will feel the urge to step out of the laboratory and to look at the field as a whole." In these words Dr. H. E. Sigerist introduces his translation of Maurice Arthus's essay on *The Philosophy of Scientific Investigation*.<sup>1</sup> Early in life Prof. Arthus fell under the spell of

Claude Bernard's methods and applied them faithfully. Bernard, when he reached some conclusion, criticized it with the firm determination to demolish it if possible. When in spite of all efforts he did not succeed in pulling it down, then and only then did he accept it as valid and publish it. This rigorous method if generally followed would probably diminish the output of scientific literature considerably. Arthus became known in this country in the last decade of the nineteenth century for his work on the coagulation of blood, but his main work was on anaphylaxis. He would stress to his students that though a fact is always interesting it only acquires significance if properly interpreted, just as a work of art acquires its complete value only if properly placed and properly lighted. Hence the experimentalist attempts an interpretation—that is, he makes a hypothesis—which should be merely regarded as a question, calling for further inquiry. "Seek facts and classify them—and you will be the workmen of science. Conceive or accept theories—and you will be their politicians." For, as he points out, once a theory is accepted it is likely to become a dogma which must be defended rather than proved. He sharply contrasts the rigidity of the fact with the plasticity of its interpretation. The saying that "the exception proves the rule" is often repeated, forgetful of the fact that "proves" was here used in the old sense of "tests" or "probes." It is indeed the exception that tests the rule, and this Arthus clearly recognized. "A well-outlined subject, a question clearly put, an experiment able to lead to a unified solution, a categorical answer—these are some of the conditions required for a fruitful experimental investigation."

It is interesting to compare this with the method recommended by Francis Bacon in his famous *Novum Organum*, so long regarded as the introduction of modern scientific method. Historically this is not correct, for William Gilbert (the quatercentenary of whose birth has been recently commemorated) was beyond doubt the father of experimental science in England, and his *De Magnete* published in 1600 antedated all Bacon's theoretical contributions to the subject. Without belittling Bacon's influence, it is fair to say that we are now in a better position to assess the value of his contributions than were those who were dazzled by his great name and fame. He was right in believing that the collection of authenticated facts was the urgent need of his age, but wrong in believing that the results would emerge by passing all the facts through a logical mill. Prof. Major Greenwood recently went so far as to say that "Bacon was not a much more useful teacher or textbook writer than the despised ancients." This is severe indeed, but the most serious defect in Bacon's system was his claim that it went far to level man's wits and left little to individual excellence. This might appeal to some of our modern planners, but never was there a greater fallacy. It leaves out of account the scientific use of the imagination. Arthus, on the other hand, believes in this so long as it is carefully controlled by the test of further experiment. Bacon believed in induction as sufficient alone; Arthus recommends induction with a collection of facts and then deduction from the hypothesis thus reached, to be tested by a second process of induction before a generalization is reached.

<sup>1</sup> Maurice Arthus's *Philosophy of Scientific Investigation*. Preface to *De l'Anaphylaxie et de l'Immunité*, Paris, 1921. Translated from the French, with an introduction by Henry E. Sigerist. (Pp. 26; \$0.75.) Baltimore: Johns Hopkins Press.

The scientific investigator, in Arthus's view, requires more than intelligence: he needs character. His path is littered with obstacles, and he must have tenacity, with the capacity to distinguish this from the obstinacy that persists in exploring a blind alley. He must also be able to obtain stimulus from his teacher without surrendering his independence. The way of the investigator, as he sees it, is hard, but the rewards for following it faithfully are satisfying.

### BOVINE SERUM FOR TRANSFUSION

Reports from the battle fronts and from bombed cities have all emphasized the urgent need for early and often large transfusions for about 13% of casualties. For this purpose there has so far been no satisfactory substitute for human blood or its derivatives. It would clearly be an enormous advantage if animal proteins prepared from animal serum could be used, since they are available in almost unlimited supply, and with present events such abundant supplies would be most welcome. Both in this country and in the U.S.A. attempts have been made to employ ox serum for transfusion purposes. F. R. Edwards<sup>1</sup> has already reported in this *Journal* a preliminary clinical trial of a preparation of despeciated bovine serum. He found that treatment of bovine serum with sodium sulphate to remove the globulin fraction, which theoretically should contain most of the antibodies, resulted in a solution of albumin which gave severe reactions in two volunteers. He then tried to destroy the antibodies by heating, coagulation being prevented by addition of formaldehyde and ammonia. The final preparation contained approximately 5 grammes of protein per 100 c.cm., and was, he suggests, "a mixture of albumin and an agglomerated form of protein." The results of the administration of this fluid in amounts varying from 400 to 2,400 c.cm. to 26 patients with a variety of conditions are given in tabular form, and more detailed notes on two of the patients only are also available. Pyrexia and vomiting were recorded in three instances only. Considering that the majority of the patients were medical rather than traumatic cases, the lack of any reaction is most remarkable.

Much work on somewhat the same lines has been carried on in the U.S.A. Both whole ox serum and purified albumin prepared by Cohn's process have been used, with extremely conflicting results. Heyl, Gibson, and Janeway<sup>2</sup> have studied the effects of concentrated solutions of human and bovine serum albumin on blood volume after acute loss of blood in man. They describe no toxic effects other than the appearance of urticarial wheals from the ox concentrate, and claim that there was no significant difference in the effect on blood volume after the administration of ox or human albumin. The rise in plasma volume in all cases was much greater than the volume of the concentrated albumin solution injected, indicating, they conclude, that extra fluid had been added to the circulating plasma from the body's own reserves. Since extremely rapid over-dilution may occur immediately after haemorrhage in healthy individuals without the administration of albumin preparations (Dyson, Plaut, and Vaughan<sup>3</sup>), it is doubtful whether this interpretation of their results is correct. Dunphy and Gibson<sup>4</sup> have also reported experimental studies on dogs which suggest that bovine serum albumin may be as satisfactory as dog plasma in maintaining plasma volume and blood pressure in experimental shock. The

detailed and careful immunological studies published by Janeway<sup>5</sup> would, however, suggest that extreme caution should be exercised in the use of animal blood derivatives, however attractive they may be on theoretical grounds. It is clear that bovine serum will maintain blood pressure as well as human serum, and that it can be utilized by the human body, but it is equally clear that preparations now available may cause highly unpleasant and in some instances delayed reactions not unlike serum sickness. This is not surprising when it is remembered that, though bovine and human albumins prepared by the low-temperature alcohol-water method have almost identical chemical properties, they differ much when tested immunologically. Further, it is clear that cross-reactions occur between bovine albumin antisera and therapeutic horse sera used as antigens. This is of practical importance because so many horse antisera are employed to-day in the treatment of disease. Janeway, for instance, reports two subjects who had previously had horse serum, followed by severe sickness; they were given 8 and 12 grammes of bovine albumin respectively: one developed very severe serum sickness, and the other a strongly positive skin test for bovine alpha and beta globulin.

As Heyl and his colleagues themselves say: "No statement regarding the safety for intravenous use . . . can be made until more extensive clinical tests have been completed in order to determine to what extent and under what circumstances it will be safe to use a protein of animal origin in man." The use of such proteins is clearly not an immediate practical proposition. The millions of blood donors enrolled in the Emergency Medical Service still have an urgent job to do for the country.

### REHABILITATION OF INJURED MINERS

The development of rehabilitation for injured miners throughout the coalfields of Great Britain was the task accepted by the Miners' Welfare Commission in the autumn of 1942. Mr. R. Watson-Jones was appointed honorary director of rehabilitation, and he was assisted by a medical advisory committee. Rapid progress was made. Seven residential rehabilitation centres have already been opened in England, Scotland, and Wales; others are in preparation; six special hospital centres are available, and out-patient facilities are being developed. There is now provision for half a million miners, and within the next few months the requirements of over 90% of the industry will have been met. The special centres are provided with x-ray and plaster rooms, gymnasiums, treatment cubicles, recreation rooms, and playing fields. Surgeons are appointed jointly to the rehabilitation centre and to the associated fracture A hospital; they are assisted by physical training instructors, occupational therapists, and physiotherapists. Special members of the staff are responsible for problems of resettlement and retraining; management is governed by committees composed equally of miners and mine owners. The medical rehabilitation committee of the commission, responsible for central planning and administration, has been strengthened. Members appointed under the chairmanship of Mr. Watson-Jones include: Mr. H. A. T. Fairbank and Prof. H. Platt (Ministry of Health), Dr. Donald Hunter (industrial medicine research), Dr. S. W. Fisher (Ministry of Fuel and Power), Sir Robert Stanton Woods (physical medicine), Mr. Alexander Miller (vice-chairman of committee), Mr. I. S. Smillie (Gleneagles), Mr. F. W. Holdsworth (Sheffield), Mr. C. S. Walker (Stoke-on-Trent), and Mr. E. A. Nicoll

(consulting surgeon to the committee). Mr. Trevor Evans is surgeon to the South Wales centre, Mr. J. B. Leather of Birmingham consulting surgeon to the Midlands centre, Mr. Gordon Irwin of Newcastle consulting surgeon to the Northumberland and Durham centre, and Mr. W. S. Diggle of Liverpool consulting surgeon to the Lancashire, Cheshire, and North Wales centre.

The physical hazards of mining are greater than in any other industry. One miner in every five sustains injury every year. This must be accepted by the miner as part of his contract, and he has the right to expect the highest possible standard in the treatment of his injuries. It is therefore with satisfaction that recent developments in the treatment of injured miners can be recorded—developments which will serve as an example to other industries in future years.

### PREFRONTAL LEUCOTOMY

Prefrontal leucotomy has now been practised for seven years in the U.S.A. and for over three years in this country. Enough experience has been gained for sober stock to be taken of its position, and Fleming's scholarly paper<sup>1</sup> is both welcome and timely. Watts and Freeman<sup>2</sup> have analysed the results of 136 personal cases: of 62 cases of involutional depression 37, at the time of writing, were employed and 11 others were at home; of 30 obsessive-tension states 21 were employed and 7 others at home; and of 31 schizophrenics 15 were employed and 11 others at home. Ziegler,<sup>3</sup> in a survey of 618 cases from 18 centres in the U.S.A. and Canada, finds that 214 recovered and 251 were known to be working part or full time. Comparable results have been found in this country. Bearing in mind that it is usual to employ leucotomy only in cases of bad prognosis and mainly after other forms of treatment have failed, these figures are encouraging. The operative mortality is not high: in Ziegler's 618 collected cases it was under 2%, in Watts and Freeman's series 2.2%, and McKissock<sup>4</sup> has had only 3 deaths in over 200 operations. Neurological sequels are few, the only common one being epileptic fits, which occur in some 10% of cases. Changes in personality may follow, but for the most part consist of a welcome release from emotional tension. This release may bring about a rather too care-free attitude to life. Freeman and Watts<sup>5</sup> observe that "some remain somewhat indolent, lacking in the imaginative capacity to see for themselves what needs doing. Others are freed from the restraints imposed by timidity, sensitiveness, or embarrassment, and they can carry on quite undistracted by their inner thoughts." There may be in some "a certain abruptness in manner and speech, a certain buoyancy, an enthusiasm, an ingenuous personality, even an exuberance, that is at times rather trying on the close associates." In judging the advisability of leucotomy these are the main dangers to be weighed against the degree of severity and intractability of the disease in each individual case. Kisker<sup>6</sup> deplors that the operation is condemned by some on the ground of vague "principles."

In addition to its therapeutic value, leucotomy has given an impetus to researches on brain function. Freeman and Watts see the main personality change resulting from leucotomy as a lack of ideation concerning the self and the future of the self. To them this loss of self-consciousness and of personal imaginative foresight seems to indicate that these attributes are especially highly integrated functions of the frontal areas. Cobb<sup>7</sup> criticizes these conclu-

sions. He does not believe that any special quality of behaviour is lost, but that the multiple association paths, normally traversed before civilized man's speech or action, are short-circuited by section of the fronto-thalamic fibres. He considers "long-circuiting" to be the essence of the problem. Using Fulton's term, "long-circuiting," to describe "the mechanism that allows spread of impulses from one reflex level up and down to other segments," he points out that it allows for an enormous increase in association, gives higher integration, leads to delayed action, and allows the past experience of an individual to affect his behaviour. In Cobb's view it would seem that the patient who has undergone leucotomy is relieved of his morbid type of cerebration, not by elimination of any specialized centre for foresight or other quality of thinking but by a general cutting out of association circuits. By this interpretation he explains quite logically Freeman and Watts's finding that the more white matter is cut the better the results.

### ANOMALIES OF LEFT COMMON ILIAC VEIN

Almost forty years ago McMurrich<sup>1,2</sup> described a series of obstructive anomalies of the mouth of the left common iliac vein. These observations have now received very complete confirmation in a recent paper by Ehrlich and Krumbhaar<sup>3</sup> which records the detailed examination of 399 cases. The left common iliac vein showed a definite obstructive anomaly in no less than 23.8% of the cases, and a further 4% were possibly slightly obstructed. These obstructions were in the nature of fibrous thickening and adhesions, and all occurred at the mouth of the left common iliac vein at its entry into the inferior vena cava. The obstructing lesions could be analysed into five groups: thickenings of the outer part of the vein wall; similar thickenings, with one or more secondary venous channels passing along the outer wall of the vein; antero-posterior or other bands crossing the mouth of the orifice; obstructions affecting the medial vein wall; and, finally, a miscellaneous group of lesions. Only exceptionally was there any narrowing of the vein lumen immediately below the obstruction. The histology of the lesions is not reported in any detail, but the authors state that the obstructed regions showed a great deal of elastic tissue, some collagenous tissue and smooth muscle cells, but no inflammatory cell infiltrations or irregular arrangement of scar tissue. An analysis of the age incidence suggested that few, if any, of the obstructing lesions were developmental in origin, but that almost all appeared during the growth period, and rarely after adolescence. An item of considerable interest is the fact that the obstructions were at the point where the right common iliac artery crosses the left common iliac vein. Ehrlich and Krumbhaar think that the anomalies they record have an important clinical significance in connexion with the greater frequency of deep venous thrombosis in the left lower limb than on the right side. On the other hand it is impossible to agree with them when they suggest that the venous anomaly has any bearings upon idiopathic varicosity, which does not show such striking difference in incidence between the two sides.

We much regret to announce the death of Prof. J. Shaw Dunn, M.D., who had held the chair of pathology in the University of Glasgow since 1936, in succession to Sir Robert Muir. Before returning to Glasgow in 1931 as Notman professor he had been professor of pathology in the University of Birmingham and in the Victoria University of Manchester. Our obituary notice will appear in a later issue.

## Reports of Societies

### THIOURACIL FOR THYROTOXICOSIS

A meeting of the Section of Experimental Medicine and Therapeutics of the Royal Society of Medicine was held on June 13, under the chairmanship of Dr. R. D. LAWRENCE, for a discussion on thiouracil in the treatment of thyrotoxicosis.

#### Clinical Experience in 32 Cases

Prof. H. P. HIMSWORTH reported on a clinical experience of this drug in 32 cases at University College Hospital. Of these, 26 were under his direct care and 22 had been observed beyond the stage of initial treatment. The longest period of observation had been 10 months, the shortest 10 weeks. Seven of the cases were started on thiourea, which alone was available at that time, but were turned on to thiouracil as soon as possible. The latter did not produce the vomiting, conjunctivitis, and smelling breath associated with thiourea, otherwise the drugs seemed to be alike. The dosage of thiourea was 1 gramme three times a day, and of thiouracil 0.2 gramme five times a day. The average duration of the initial course was 29 days. In no case did the treatment fail to effect conspicuous improvement, and none became drug-resistant. All patients gained weight, the basal metabolic rate and the pulse rate fell, and the plasma cholesterol went up. Sweating, skin flush, and nervousness disappeared, and diarrhoea, if present, stopped. In one of the two patients who had fibrillation, regularity was restored during treatment. The exophthalmos was not noticeably altered, and the goitre appeared in the majority of the cases to be unaffected; in two there was an increase in the size of the goitre during treatment, and the patient had to be operated on. The drug acted neither immediately nor uniformly upon the symptoms. There was little change in the pulse for a fortnight after treatment had started, but by the end of a month the pulse became normal. The first symptom to disappear was the skin flush, the last the quickened pulse. Three cases said to be resistant to thiouracil had been referred to him, but in each of them he found improvement, which indicated that the disease was coming under control, and the conception of resistance was evidently based on the fact that the pulse was still rapid.

From this it appeared that under thiouracil the symptoms and signs of thyrotoxicosis could be rapidly and effectively controlled, and the results of the initial treatment were at least comparable with those of surgery. Far smaller doses were needed for maintenance than for establishing control. One patient was put on a maintenance dose only one-fifteenth of that given at the beginning, and yet maintained increased weight, and there was no return of symptoms. The majority of patients were able to resume full work after a period of up to three months. It was too early to say whether treatment by thiouracil could be given up and the patient remain well, but two of the patients who had gone off thiouracil, for 7 and 10 weeks respectively, had maintained their improvement.

#### Untoward Effects of the Drug

If thiouracil had no untoward effects it would be reasonably certain that here was a cure for Graves's disease, but unfortunately it had an untoward effect, and only experience would show whether the drug was more dangerous than operation for removing the gland. Symptoms of overdosage must be distinguished from manifestations of idiosyncrasy. By the former he meant such symptoms as would be produced in any patient by giving too much of the drug. Such symptoms were divisible into two groups—gross overdosage manifesting itself by an increase in the size of the gland, and chronic overdosage in which the symptoms were more subjective. The patient might go on perfectly well on a small dose of thiouracil for months, and then come up with a condition superficially suggesting hypothyroidism, though there were no sure indications of that. This condition coincided with a sharp jump upwards of the blood cholesterol. To avoid these reactions the dose should be reduced to the minimum needed to maintain the weight.

Symptoms of idiosyncrasy appeared capriciously: fever, rashes, enlargement of lymph glands, swelling of legs and feet, and blood changes had all been reported. These appeared within a week or fortnight after starting the drug, and did not appear late in maintenance treatment. The most serious manifestations of idiosyncrasy were agranulocytosis, leucopenia, and thrombocytopenia. In the 32 cases mentioned there had been 2 of leucopenia and 1 fatal case of agranulocytosis. This patient had had 1 gramme of thiouracil a day for a month and proved completely resistant; she had previously been given iodine for two years on end. The dose was then pushed up to 2 grammes, and the thyrotoxicosis responded, but eight days after her discharge she developed a whitlow, and after that shivering and other signs; she was readmitted and given blood transfusion, but contracted bronchopneumonia and died. It was quite clear that there was some question of idiosyncrasy involved. The drug did not cause a steady depression of the white cells in all people. Of Prof. Himsworth's own 22 patients the white blood count on admission had ranged from 4,000 to 10,000, average 6,500, and the polymorphonuclears from 42 to 80%, average 59%. After one month's treatment the white blood count ranged from 3,000 to 11,000, average 6,800, and the polymorphonuclears from 40 to 81%, average 60%. When leucopenia appeared it appeared suddenly in patients whose previous blood counts had been normal. There was an indication that the development of agranulocytosis was influenced by the amount of drug given, not the total spread over many months, but the intensity of the daily dosage. They were now hoping to avoid trouble by giving small doses—0.5 gramme a day during the initial period and 0.1 or 0.05 as quickly as possible. The treatment was experimental, and patients should not be given this drug except under close, detailed, and continual investigation.

#### Nine Documented Cases

Mr. CECIL A. JOLL (whose paper was read for him in his absence) said that opinions at this stage could be scarcely more than tentative. Some of the more optimistic statements made in this country were, at any rate, ill judged. The name "thyrotoxicosis", embraced a number of diseases, of which Graves's disease was best understood, easiest to diagnose, and in some ways easiest to treat. The knowledge of thiouracil had been gained in connexion with Graves's disease, and little or nothing was known about its application in the larger and more insidious and hazardous group of cases included under the heading of secondary thyrotoxicosis. The number of cases of thiouracil treatment which his team had been able to observe was between 20 and 30, but many of these patients were not prepared to remain under direct observation for as long as was thought desirable, and he limited his paper to 9 cases which were fully documented. So far as the others were concerned, they did not show any appreciably better results. In 6 of these 9 cases the results were favourable and in 3 the reverse. Of the favourable cases 3 were mild, 2 severe, and 1 moderately severe. In one of the favourable cases the response was satisfactory, and the basal metabolic rate and the pulse rate came down; but the patient said she felt no better and asked for operation, which was performed. In the three unfavourable cases, after lack of satisfactory response to the drug, operation was carried out. Mr. Joll hoped that treatment with thiouracil would be allowed only under strict control, and that manufacturers would not release these powerful and dangerous drugs to all and sundry.

#### General Discussion

Dr. E. P. SHARPEY-SCHAFER said that at Hammersmith Hospital about 30 cases had been treated and had done extremely well. It seemed likely that these substances might be beneficial in other conditions—for example, in very severe chronic congestive heart failure. There was some evidence of the action of thiouracil on the normal thyroid. While at the end of a week or ten days there might be no histological changes in the normal thyroid after 2 grammes a day, such changes might occur if the administration was continued, and he showed a photomicrograph of a biopsy section of normal thyroid which had had this dosage, and drew attention to the absence of colloid and the considerable increase in height of the epithelium. He suggested that the Medical Research Council might be asked

# Correspondence

JUNE 24, 1944

to collate and prepare a statistical analysis of the evidence concerning the dangers of these drugs and issue some advice on the subject.

Dr. HORACE EVANS said that he had had an opportunity of observing 12 cases at the London Hospital; in all of them the results were demonstrably satisfactory, and no serious ill effect had been produced; in one there was slight leucopenia. Dr. G. MELTON spoke of the effect on auricular fibrillation, and related the case of a woman, aged 65, with severe thyrotoxicosis, whose rhythm was restored to normal after about a fortnight on thiouracil—a result confirmed by the electrocardiograph.

Dr. S. LEVY SIMPSON said that although Prof. Himsworth's opening statement had a tinge of optimism, and Mr. Joll's an accent of scepticism, the results described by both were very much alike. There was no doubt that in a large proportion of cases thiouracil did lower the pulse rate and the basal metabolic rate to normal or below normal, and the patients under treatment. Apparently the drug prevented the synthesis of thyroxine, in the size of the gland might be anticipated. He was convinced that thiouracil was a valuable and potent drug which, either in its present form or in some modified form, would find its place in therapeutics; but it was a potentially dangerous drug and at present should be used only by those who had specialized knowledge and were capable of observing their cases closely.

Prof. HIMS WORTH said that among the cases he had brought forward were a considerable number with secondary thyrotoxicosis, and he had no reason to suppose that they differed in their response to thiouracil from the improvement in decrease in the basal metabolic rate and the improvement in the clinical condition seemed to him exactly comparable in both sets of cases. If he might be allowed to criticize Mr. Joll's three "failures," it was not without significance that in every one of them iodine treatment had previously been given, and that two of them had been on thiouracil for three weeks and the third for four weeks, and then the administration had stopped; this in a patient who had been on iodine might be quite insufficient to show any effect on the pulse rate.

In an address on recent work on viruses at a meeting on June 2 of the Whipp's Cross Hospital Medical Society Prof. S. P. BEDSON described the psittacosis group, their relation to other viruses of similar morphology, and the interesting finding that some cases of atypical pneumonia were due to the virus of the psittacosis group, and that the natural hosts of this disease included in addition to birds of the parrot family, the fulmar petrel, the domestic fowl, pigeons, and possibly other bird species. He said that recent work had shown that herpes labialis in adults was the result of a carrier condition set up in infancy during an attack of herpes stomatitis. Thereafter host and virus lived in equilibrium and herpes only appeared when some intercurrent trouble upset the balance. Dismissing the mode of spread of poliomyelitis Prof. Bedson pointed out that the earlier and apparently convincing evidence incriminating the nasopharynx as the portal of entry was seriously questioned by recent American work, which demonstrated that the virus excreted in the stools, infection being probably spread by food contaminated by hands or possibly by flies; the absence of explosive epidemics suggested that infection was not water-borne. The lecture was illustrated by lantern slides, and aroused much interest. It was announced at the meeting that the Society intended to invite outside practitioners to join who would be circularized as soon as rules for membership had been agreed on. Meetings will not be held during July and August.

At a recent meeting of the Maternity and Child Welfare Group of the Society of Medical Officers of Health Dr. DOYNE BELL gave an address entitled "A Reassessment of some Paediatric Procedures," in which he discussed, among other subjects, the indications for circumcision and for tonsillectomy; tongue-tie; the physiological variation in the period required for the establishment of lactation; the technique of breast-feeding; the treatment of the breast-fed baby. He also dealt with the use of sedatives for the "crying baby," the treatment of bronchitis in infancy; the advantages of national dried milk over patent foods; and the low value of ultra-violet light as a source of vitamin D.

## Dictary Surveys

SIR.—The remarks by Miss E. M. Widdowson and Dr. R. A. McCance to the Nutrition Society, as reported in the *Journal* (June 10, p. 792), add point to a situation which may be described as follows.

If, ignoring the question of quality, there is, as is the case, complete ignorance of what constitutes an adequate amount of any one single nutrient substance; if the amount of these nutrient substances, as again is the case, varies in quantity in foodstuffs according to the locality of growth, manurial treatment, season, variety of plant, parts used, and other factors; if, as happens to be the case, the price of foodstuffs varies considerably from place to place and in the same place according to the social status of the purchaser; if, as is true, the point is not how much is *actually spent* on food but how much *could be spent* if it were not for the existence of ignorance and "luxury" spending, then it is difficult to see how anyone could say, as Orr and those who quote him do, that a certain proportion of the population is suffering from malnutrition because of lack of money wherewith to purchase an adequate diet.—I am, etc.,

J. P. MCGOWAN.

## Pulp Infection of the Fingers

SIR.—It is with the utmost satisfaction that I read the article on pulp infection of the fingers (June 10, p. 782), coming as it does from a member of the Forces. An inestimable amount of invalidism and permanent disability is caused by such infections, largely due to failure to appreciate the points enumerated by Major Denness. I would emphasize several additional facts in regard to treatment.

- (1) The ethyl chloride spray has no part whatsoever to play in the treatment of pulp infections. This, in my opinion, has in the past been the largest single factor in producing disasters. It now has a strong rival in the sulphonamide group of drugs.
- (2) Incision is most easily made and controlled while the finger is steady and rendered avascular by a strip of gauze held tight round the base of the finger.
- (3) The U-shaped incision taken round the tip of the finger close to the end of the nail is not mutilating; in fact the scar is often invisible so far proximally that the flap can easily be turned through a right-angle; if this is done no indwelling "drain" is necessary, and very infrequent interference with the wound is required.
- (4) Bandages should be dispensed with at the earliest opportunity, means of allowing free movement; even this should be left off for periods during the day while the patient practises active movements of the terminal interphalangeal joint with the middle phalanx held steady.

Only a primary subperiosteal infection or delay on the part of the patient in seeking advice can excuse bone necrosis. In every other case it is the practitioner or surgeon who is culpable and who should seek guidance in the hard school of self-criticism rather than in pondering whether he gave the proper dose of the proper sulphonamide!—I am, etc.,

D. J. ROSS STEEN, F.R.C.S.

Weymouth.

SIR.—The paper on treatment of pulp infection of the fingers in the field by Major T. Denness is of much interest, while it should be found of great value to all who have to deal with these important infections.

There are three points, however, that warrant further discussion.

- (1) Major Denness advocates the use of bilateral incisions of the pulp; I have used a unilateral incision, as described by C. L. Callander in his textbook on *Surgical Anatomy* (W. B. Saunders Company, 1939), for a large number of these infections with success. The knife is introduced into the lateral aspect of the pulp so that the tip of the knife can be felt just under the skin on the opposite side, and the incision is then made so that the whole of the pulp space is opened to allow adequate drainage; sinus forceps may be used to ensure that this is so. While on this point I would reiterate

Major Denness's remark that the incision need not be carried across the finger-tip, and I would add that it should never be, since it may result in loss of tactile sensation of the finger-tip, a notable prolongation in the time needed for healing, and often an ugly deformity of the finger.

(2) A corrugated rubber drain can still be used with the unilateral incision, although I have found that ribbon gauze soaked in a 50% solution of magnesium sulphate containing 10% glycerin is far superior, while it can be changed daily until pus is no longer present.

(3) Morphine seems to be quite out of place in the post-operative treatment, since, if the incision is adequate, the tension in the pulp space is relieved and the patient should be free from pain, and will sleep well with the help (if help be needed) of aspirin gr. x and barbitonum soluble B.P. gr. v on the first night, while he will sleep naturally on the following nights.

The need for prompt and thorough treatment is great, and, as Major Denness so rightly points out, "a man may be off duty longer with a whitlow than after appendicectomy"; that "conservative methods are unavailing" cannot be over-emphasized. In a recent letter (Feb. 5, p. 198) I showed that in pulp infections treated early the average healing time is 8.5 days, while delay can lead to a period as long as 26 days before healing takes place, and the resultant stiff finger is a cause of a further number of weeks' disability, which has its effect just as much in the factory as on the battlefield.—I am, etc.,

Surbiton Hospital

PHILIP HOPKINS.

### Volkmann's Ischaemic Contracture

SIR.—The article by Mr. G. A. Pollock (June 10, p. 783) is extremely opportune, as the question of ischaemia in general is worthy of the fullest consideration.

The statement from a textbook on orthopaedic surgery which is quoted by Mr. Pollock is one with which most will agree: but the question of early surgery must surely be for the ischaemia and not for the established deformity.

I was tempted to conclude from Mr. Pollock's article that he was not in agreement with the widely established view that ischaemic contracture is caused by arterial vasospasm. In a recent article on ischaemia I tried to collect the clinical and experimental evidence and show that vasospasm most commonly results from afferent impulses arising within the arteries themselves. Thus vasospasm may be limited to section of the artery above and below the site of origin of the afferent impulses, or it may involve the distal part of the artery completely. In the case of the radial and ulnar arteries one can be involved without the other. Thus, although the anastomosis between the radial and ulnar arteries is excellent, a vasospasm in either will seriously affect any structures which are supplied entirely or even almost entirely by that section of the artery in spasm. For example, I saw a man recently who was alleged to be the subject of Buerger's disease. He had already had a bilateral lumbar ganglionectomy; now the upper limbs were affected. One index finger was gangrenous at the tip and the condition seemed to be progressing. This was in spite of a good strong ulnar pulse, the radial being absent.

Wounds of large arteries by shell fragments, etc., are commonly associated with local vasospasm for which excision seems to be the best treatment. Thus it is, in spite of the seriousness of the injury, very little haemorrhage occurs. Unless these wounds are explored the vasospasm may be missed and in consequence gangrene or ischaemic contracture may result.

Adverting to the case described by Mr. Pollock, the history strongly suggests that the ulnar artery, as the result of trauma, became the site of a local vasospasm. No massive contracture could develop as the radial artery was intact. It would be interesting to know if there was an ulnar pulse at the time of examination, as the presence of a radial one does not affect the issue and, somewhat paradoxically, neither does the presence of an ulnar pulse, as the artery may be in spasm only to a limited extent. Even so the amplitude of the ulnar pulse might be much less than the radial.

The case history described by Mr. Pollock indicates a complete lack of infection. Thus a secondary haemorrhage on the twelfth day would seem unlikely unless the "secondary haemorrhage" were due to relaxation of a vasospasm. The

small disability caused in this case seems most likely to be due to the extremely limited area of muscle affected by the lack of ulnar blood supply. The somewhat late operation for a Volkmann (20 days after injury) was probably timely enough, in that gross changes resulting from ischaemia had not yet occurred or could not occur.

This letter is not intended in any way as a criticism of Mr. Pollock's article. It is merely a different approach to the matter in the interests of discussion. When one is faced with making the decision whether to explore a wound or not it requires considerable thought and may be luck to be right in every case. Most surgeons would have followed Mr. Pollock exactly up to Dec. 24; I doubt if most would have decided to explore at that time under the circumstances, though the end-result proved the wisdom of so doing.—I am, etc.,

Wembley.

J. SHIRLEY CALLCUTT.

### Cerebral Malaria

SIR.—I have read with interest the article by Dr. I. B. Sneddon in the *Journal* of Dec. 25, 1943, regarding the above, and also the letter on the same subject by Drs. G. B. Young and C. J. A. Macaden published on May 13 of this year. It seems to me unfortunate that so much emphasis is placed on the more severe types of cerebral infection—maniacal excitement, coma, etc. In my own experience as a neuropsychiatrist it was the milder types that were the more frequent and which occasioned the greater problem. For example, it was not uncommon to meet with a soldier who was accused of being drunk and disorderly suffering from cerebral malaria, or another absenting himself from his unit and found wandering. Further, many cases of sudden impulsive violence met with in the Far East I have demonstrated as being caused by a quartan cerebral infection. Neglect to recognize these cases is most unfortunate to all concerned.

With regard to the immediate treatment of severe cerebral malaria, I am of the opinion that local experience should always be consulted. In hospitals receiving patients from over a wide area it is wise to chart out the different schemes for reference, as the results obtained are vastly superior to any dogmatic plan. With this information available I have frequently given 10 gr. of quinine intravenously with excellent results. Where no experience was to hand 3 gr. of quinine well diluted and given very slowly should be tried, and, if no improvement takes place and no intolerance is noted, repeated in two hours.

In special practice one receives cases from many practitioners, and it may be that I have obtained an unfortunate concept of the incidence of quinine abscess as being by no means rare. When one recalls the amount of crippling and tissue destruction occasioned by a quinine abscess I am most reluctant to commend the intramuscular method to anybody.

In conclusion, I am of the opinion that it is wise to prescribe a course of psychotherapy in all cases of cerebral malaria, mild or severe. I believe, if this course was adopted, a large number of the dreadful tragedies which are not an uncommon sequel would be obviated.—I am, etc.,

Walkden, Lancashire.

D. FENTON-RUSSELL.

### Chemotherapy in Otitis Media

SIR.—It is most desirable that attention should be directed, as in Mr. Dingley's paper in your issue of June 3, to the dangers of sulphonamide therapy in acute otitis media, but I think he goes too far when he says, "The wholesale use of sulphonamides in otitic infections is to be deprecated." Mr. Dingley's antsulphonamide views are those of an otologist, but, after all, the real authority on the value of chemotherapy in early acute otitis is not the otologist but the general practitioner; he sees the cases which get better, the otologist as a rule only sees the ones which don't. Before sulphonamides were introduced my wife developed acute otitis, and I got a colleague to do a myringotomy; after their introduction my son was similarly afflicted, and I called in a good general practitioner as likely to know more about the behaviour of inflamed drums in the early stages under sulphapyridine.

My friends in general practice all say that the great majority of acute ears subside quickly and completely with sulphonamides. But, apart from evidence of frank mastoiditis, if

all the signs of simple acute otitis (whether the drum bursts or not) have not completely subsided in 10 to 14 days under adequate chemotherapy (and this for an adult means not less than 1 g. 4-hourly and not one tablet t.d.s., as one still sometimes finds given), an otologist ought to be called in at once. Under these circumstances the persistence of a profuse discharge alone is strong evidence that the mastoid is infected, and the persistence of any discharge at all a warning to be on the look-out for trouble.

My own experience of mastoid operations is that before the days of sulphonamides one encountered many more mastoids, but of these a very small percentage had complications; nowadays I do a fraction of the pre-war number of mastoids, but among them an enormously higher proportion come up with complications such as intracranial infection, sinus thrombosis, and septicaemia. The reason is as Mr. Dingley points out, that if the infection is not eradicated but merely suppressed it grumbles away silently in the mastoid till it gives rise to serious trouble. As regards myringotomy, I have almost packed away my myringotome: first, because I do not see the acute ears, since the general practitioners cure them; and, secondly, because I have been disappointed with the results of myringotomy in conjunction with sulphonamides—instead of the expected gush of pus I have often felt that I have only incised an oedematous drum and not really done any good.

Perhaps Mr. Dingley would say that if I got at the ears earlier and incised them without chemotherapy I wouldn't see so many complicated mastoids. I think the answer to that is that what is at fault is the non-realization of the damping-down effect of sulphonamides, particularly in insufficient dosage, and that to discourage general practitioners from using chemotherapy for acute otitis would do far more harm than good.—I am, etc.,

Guilford.

G. H. STEELE.

### Chemoprophylaxis of Gonorrhoea

SIR.—In your review of Dr. Herrold's book (June 3, p. 753) you state: "Apparently prophylaxis not only for Service men but for civilians is recommended; a warning is wisely uttered against the use of oral sulphonamides for this purpose." The last clause does not accurately represent Dr. Herrold's views. On page 91 of his book he says:

"This method of prophylaxis is not without danger because the incidence of patients previously sensitized to sulphonamides is likely to increase as time goes on. Such prophylaxis, therefore, is more safely given in close co-operation with a physician. Should oral chemotherapy prove efficacious, additional prophylaxis should be given for the prevention of syphilis. From a practical-view, therefore, the exposed individual should report for both measures of prevention and should not be given a quantity of the particular sulphonamide as a precautionary measure to be taken before or at the time of exposure."

Self-medication by sulphonamides is to be deprecated, but medical practitioners should not be dissuaded from prescribing, on the day following exposure, a method of prophylaxis of proved efficacy—e.g., three doses at four-hourly intervals of sulphathiazole or sulphadiazine, 3 g., 2 g., and 1 g. It should be added that in individuals whose work calls for a high degree of visual and mental efficiency such use of these drugs is inadvisable.—I am, etc.,

May and Baker, Ltd., Dagenham, Essex.

ROBERT FORGAN.

SIR.—I am interested to see your article (May 20, p. 695) on sulphonamide prophylaxis of gonorrhoea. The question of prophylaxis for this disabling disease is of prime importance, but I feel that one important observation has been omitted from the article which would prevent me from using it in the manner described, unless my views on the matter undergo a radical change in the light of the opinion of experts.

My objection is this: the administration of sulphathiazole prophylactically carries with it the danger that by its very administration we may hide those symptoms which are sometimes the only indication of the presence of the disease, a disease which a man is usually most anxious to hide, and which, in the absence of symptoms, he may not report at all. If sulphonamide is given prophylactically it is at the best a very "hit-and-miss" method, and cannot be subjected to critical analysis or results accurately assessed. I feel that if a man

has had prophylactic treatment it is very difficult to state whether he has (a) had the disease and been cured (a deduction which can only be made from the man's own statement), (b) has not been infected at all, (c) has got a latent form of infection without any external symptoms. In addition to this, it is surely axiomatic that wherever possible a patient should be allowed to develop his own immunity before calling in the aid of drugs.

I am not a venereologist and probably the factors I have mentioned can be satisfactorily answered by one with greater knowledge than myself, but at present I would be chary of introducing a form of preventive treatment over which I felt that I had little or no control, and the results of which I was unable to check with any degree of accuracy.—I am, etc.,

KENNETH G. BERGIN, M.B., B.CH.,  
Squad Ldr., R.A.F.

### Expectation of Life in Urinary Tuberculosis

SIR.—The case reported by Mr. Victor Bonney in your issue of May 20 illustrates the fact that Nature can effect what is to all intents and purposes a complete cure of tuberculous lesions of the urinary tract. Further examples are provided by two cases I saw some years ago.

1. X-ray examination of a lady aged 80 after an injury to her back revealed the fact that the right kidney and ureter were completely calcified. She informed me that she had had severe frequency, dysuria, and haematuria at the age of 20. These symptoms persisted for several years, then gradually disappeared. She has remained in good health since that time and has had no return of urinary symptoms.

2. A well-nourished and very active man of 60 who has attended St. Peter's Hospital for a number of years for dilatation of urethral stricture mentioned that he had been treated for urinary tuberculosis at the age of 15. His symptoms subsided after several years and he has remained in good health. Investigation showed that he had a completely functionless calcified left kidney. The left ureteric orifice was obliterated and retracted. The urine was normal.

In both these cases cure was effected by complete destruction of renal parenchyma with extensive fibrosis and calcification of the remaining peripheral renal tissue and fibrous obliteration of the ureter (so called "auto-nephrectomy"). It is obvious that a process such as this can only go on to completion when the lesion is a unilateral one, and it seems likely that in Mr. Victor Bonney's case destruction was confined to one kidney, tubercle bacilli being regurgitated from an infected bladder along the ureter of the normal side, and thus appearing in both ureteric catheter specimens. It should be pointed out, however, that spontaneous cure is the exception rather than the rule, and that there is overwhelming evidence to indicate that nephrectomy is the treatment of choice in any unilateral destructive tuberculous lesion of the kidney. In such cases surgery effects a complete and rapid removal of a progressive and (for all practical purposes) localized tuberculous focus. Nature's cure is, on the other hand, prolonged and may remain incomplete for a number of years; meanwhile the patient is exposed to the risks of spread of the infection, particularly in the direction of the opposite kidney.

The conclusion is that nephrectomy, in suitable cases of urinary tuberculosis, will on the whole increase the expectation of life, though it must be admitted that spontaneous cure will occur in a small proportion of cases not treated surgically.—I am, etc.,

JOHN SANDREY,  
Temp. Surg. Capt., R.N.V.R.

### Aerial Convection from Smallpox Hospitals

SIR.—Allow me to supplement my last letter by referring to the three letters appearing in the *Journal* of June 10.

As regards Sir Alexander Macgregor, we in Leicester also adopted the procedure he describes, and used 'not to allow members of the staff of the smallpox hospital (other than the medical officer) to go outside. After a certain spell of duty they were given long leave after thorough disinfection, and they were also paid extra salary. I am quite satisfied that "hospital operations"—apart from aerial convection—could not conceivably have accounted for the sudden and remarkable outbreak referred to in my previous letter.

As regards Dr. John Ware and his reference to the Purfleet experience, I certainly cannot agree with him that the bottom

## CORRESPONDENCE

856 JUNE 24, 1944

is knocked out of Sir George Buchanan's report because a solitary member of the staff at the hospital ships was discovered to have visited his sweetheart in Purfleet. In any case I only adduced the Purfleet experience as "strong confirmation" of the convection theory. I am glad to learn that Dr. C. J. McSweeney is one of those who have not lost faith in the theory.

Allow me to add a word of explanation to my original article. When I said that out of nineteen members who took part in the Epidemiological Society's debate seven were against the theory of aerial convection, I was including those (and they were the majority) who only said that they were not yet convinced and desired further confirmation. As Prof. Ralph Picken has shown in his letter, some confirmatory evidence has since been forthcoming, and I suggest that, but for the fact that there has been so little epidemic major smallpox in this country during the past 40 years, much more confirmatory evidence might have been forthcoming.—I am, etc.,

C. KILLICK MILLARD.

Leicester.

## Progesterone

SIR.—I would like to make a few observations on a letter from Dr. Walter Calvert (June 3, p. 772) on vomiting of pregnancy. In it he states: "I believe and teach that many of the physiological and minor pathological phenomena of pregnancy are due to the high blood level of progesterone." He then goes on to point out that progesterone relaxes plain muscle, and so produces uterine relaxation, constipation, low blood pressure, varices, and also vomiting. Acting on this assumption he has given stilboestrol in 1-mg. doses three times daily for three days with apparently good results.

In the past I have made various personal communications to Dr. Calvert, and am prompted to ask whether his views may not be based on the opinions therein expressed. If that is the case, I wish to make it quite plain that the originator of this theory, so far as I know, is Mr. Barton Gilbert, F.R.C.S., who is at present in Southern Rhodesia, and is thus unable to speak for himself. Before the war I had the good fortune to live with Mr. Gilbert for nearly a year, and during that time he propounded his theory in full so far as he had at that time worked it out. In short it was as follows: In some pregnancies the corpus luteum is more active than in others, and in some it may even be overactive. In the latter case there is an excessive amount of progesterone circulating in the blood stream, and it acts as a general relaxer of smooth muscle throughout the body. Let us consider the effects of this relaxation in further detail.

1. *The Blood Vessels.*—When the patient is in bed at night blood tends to "pool" in the dorsal region, and if the patient rises hurriedly in the morning, the column of blood at once falls to the lower extremities, producing a sudden cerebral anaemia. The patient at once tries to compensate for this by taking big breaths, in order to suck blood upwards through the action of the diaphragm. As the stomach sphincters are at the same time in a state of relaxation, and as the stomach is empty, this results in regurgitation of only a small amount of mucus into the oesophagus. Hence early morning sickness. In favour of this general relaxation of the blood vessels is the fact that slow rising in the morning is in many cases effective in combating early morning sickness. Another piece of confirmatory evidence is that transient "blackouts" are also common in pregnancy.

2. *The Intestinal Tract.*—This is generally relaxed in the early months particularly, with resulting constipation, piles, dyspepsia, and so on. I have personally had quite remarkable success in some cases of severe constipation of pregnancy by giving hexoestrol up to 10 mg. daily. I have never seen any ill effects, and have always kept a very careful watch on the blood pressure during its administration, as was suggested to me by Mr. Gilbert as long ago as 1938. As he then pointed out, the therapeutic effects of giving oestrin can be gauged by the rise in blood pressure that follows, and provided that the systolic pressure does not rise above 115 there will be no untoward effects.

3. *The Leg Veins.*—Relaxation in this situation naturally favours varices. The usual explanation is that there is "pressure" on the veins, yet in large abdominal swellings, such as fibroids and ovarian cysts, varices are not by any means the rule. Gilbert's view was that the circulating progesterone was the causative factor in the production of varices.

4. *The Veins of the Vulva.*—Similarly here too vulval varices were, he thought, due to the effects of progesterone.

5. *The Viscera in General.*—Here, as elsewhere, his theory postulates relaxation of the blood vessels supplying the part. The effect is particularly notable in the kidneys. During the early weeks when the corpus luteum is still active the kidney blood vessels may become progressively dilated, and thus stagnation of the circulation occurs. As a result the rate of blood flow becomes slower, and the effect is that the vessels, already dilated, become more and more full of blood. Finally thrombosis or haemorrhage will occur. This is of course, very roughly, the pathology of the kidney changes in eclampsia. According to Gilbert's theory, the haem. in toxæmias of pregnancy is done in the early months by the continued relaxation of the kidney vessels, and thus when the disease becomes obvious in the later weeks, by the appearance of albumin in the urine and a rise in blood pressure, it is virtually untreatable except by symptomatic measures. Logically the blood pressure could be lowered by giving more progesterone, but as this is already in excess the condition would merely be aggravated by such treatment. Again, oestrogens could be given to negate the effect of the circulating progesterone, but as oestrogens raise the blood pressure this too is illogical. The rise of blood pressure was in his view merely an indication that an attempt was being made to compensate for the kidney insufficiency, as shown by the presence of albuminuria. He felt that if only some simple means could be elaborated of estimating in the out-patient department the level of the circulating progesterone in the early months, it might be possible to treat toxæmias logically instead of empirically from the outset of the disease. Unfortunately the advent of the war cut short any further investigations along these lines.

6. *The Uterus.*—Relaxation of the uterus, with primary uterine atony, was in his view due to the same cause, and this he felt was borne out by the fact that toxæmic patients are on the whole more prone to this condition.

7. *The Placental Site.*—Continued dilatation of the vessels of the placental site favours retroplacental bleeding and the occurrence of accidental haemorrhage.

8. *The Urinary Tract.*—Relaxation of the smooth muscle in this situation favours urinary stasis, ascending infections, and thus the occurrence of pyelitis of pregnancy.

With reference once again to Dr. Calvert's letter, I too have had very good results with hexoestrol in early morning sickness and also in constipation of pregnancy, but I cannot say that the results have been uniformly good. I have on the whole given larger doses—up to 10 mg. daily—with no ill effects. Another condition that I have found will sometimes respond well is depression and loss of energy in the early months, but only if this is associated with a very low blood pressure, with systolic readings of 80 to 90.

In conclusion I would stress once again that so far as I know the whole of the theory outlined above was worked out by Gilbert as early as 1938.—I am, etc.,

London, W.1.

## Fractured Carpal Scaphoid

SIR.—I was much interested in the article on fracture of the carpal scaphoid by Jeffrey M. Robertson and R. D. Wilkins in the *Journal* of May 20. Having sustained fracture of the right scaphoid myself in 1940, there are many points in their article which apply to my own case and which I feel will not be out of place if they are reiterated.

I agree whole-heartedly with Robertson and Wilkins in stressing the importance of having all sprains x-rayed. In my own case I did not at first believe that I was suffering from anything more than a sprain of the wrist. The accident I had resulted from cranking up my car, which back-fired. I suffered some pain in the wrist which was not severe enough to prevent me from driving to the hospital that morning, and carrying out an operation list. My wrist felt very tired at the end of the morning's work, and I decided that an x-ray would be advisable. To my surprise, a small crack was visible in the scaphoid (Fig. 1b). This crack was not in the usual situation for a fracture to occur—that is, in the waist of the bone. This x-ray plate further brings out points as remarked in the article of Robertson and Wilkins—namely, the importance of taking exposure in different planes. It will be seen that in Fig. 1 no fracture is seen in position 1a and 1c, but shows up distinctly in position 1b.

Again, the authors remark on the extreme difficulty in demonstrating a fracture, in many cases, in the early stages. This is shown in my own case, as seen in Fig. 2. This was taken 20 days after the original x-ray, and it will be seen that a line of rarefaction is now beginning in the waist of the

scaphoid. Between the taking of the first radiograph on Aug. 20, 1940 (Fig. 1), and the one on Sept. 10, 1940 (Fig. 2), a radiograph was taken, but this showed no fracture in the waist, although the fissure was still present in the distal part of the bone.

I am of the opinion that in many cases of "sprained wrists" a great deal of later disability can be avoided if the precaution is taken of applying a plaster-of-Paris immobilization even in

FIG. 1

FIG. 2

those cases where x-ray examination is negative. In such cases, furthermore, it is important that radiographs be taken so as not to miss a delayed fracture which has developed owing to osteoporosis as in my own wrist.

I am much indebted to my former colleague, Mr. J. Hindenach, F.R.C.S., who treated my wrist in such an excellent manner, and to Dr. W. H. Caldwell for his radiological skill.—I am, etc.,

Slough Emergency Hospital

MALRICE LEE.

London, W.1

F. M. R. WALSH.

### Why Tie the Cord?

SIR,—I read with much interest Dr. E. W. Price's letter (June 3, p. 772), for much other evidence supports the view that ligation of the cord is normally unnecessary. This evidence has been reviewed in a book on the foetal circulation, etc., written by Dr. A. E. Barclay, Miss M. M. L. Prichard, and myself, and shortly to be published by Messrs. Blackwell Scientific Publications Ltd., Oxford. The most striking single contribution is that of A. N. Rachmanow (*Zbl. Gynäk.*, 1914, 38, 590), who was convinced by the structure of the cord vessels in man and lower animals that ligation was unnecessary, and thereafter proceeded to demonstrate the fact in several thousand confinements in a State maternity hospital in Moscow. My co-authors and I are not obstetricians, but the general trend of the evidence is such that we felt bound to conclude with the sentence: "One's only surprise is that a procedure, so firmly based upon the physiological properties of the cord vessels, has not been more universally adopted."—I am, etc.,

Oxford.

K. J. FRANKLIN.

### Medical Education

SIR,—I surmise that it is as the representative of "the practical man" that Dr. W. E. Hick (June 10, p. 796) has felt impelled to reply to my letter, and I do not dispute that there is an aspect of truth in his letter. Unfortunately, it does not contain the whole truth about the problems of medical education. It is that familiar fragment of the truth that we are never allowed to forget and that has done so much in the past to make medical education what we now deplore it to be. In the hope of making every new doctor the complete craftsman, we have overloaded the student with techniques and with masses of uncoordinated information. We have made him look on—under conditions rendering useful observation almost

impossible—at complicated surgical operations that, as a general practitioner, he will never be called upon to perform. We have inflicted no fewer than six lectures on smallpox vaccination upon him, and a vast deal of other wholly unpractical "practical" tasks. All this at the behest of generations of "practical men." We have made the cultivation of a reflective mind virtually impossible for him, and now seek to palliate our folly by maintaining that, after all, reflective minds are rare and most men prefer to occupy themselves with techniques.

Let us agree that the practising doctor should, in his proper field, be a competent craftsman, but must we confine him to this role? The pure craftsman does not add to knowledge; he simply practises and transmits what he has been taught. Is this all we ask of the doctor and of a medical education? Hitherto we have prided ourselves as forming a learned profession. Do we wish so to continue, or are we in future to be content—with Dr. Hick—to accept the motor mechanic as our exemplar and ideal? If, as I believe is the case, we do wish to remain a learned profession, then we must accept the intellectual responsibilities and privileges involved, and bear the burden of some learning over and above our bedside and laboratory techniques. We have no right to ask for a university degree on a purely polytechnic type of knowledge, and, like undergraduates in other university faculties, we must be prepared to examine the foundations of our science and to acquaint ourselves with its general principles. The university student of physics, even if he intends ultimately to be an electrical engineer, is expected to know the foundations of physics. This knowledge does not render him less efficient as an engineer, and will probably prove the basis of any additions to knowledge he may himself make.

Are we to suppose that medicine differs in these respects from other scientific disciplines, that the medical student is less willing than his fellows to think about his subject or that he is incompetent to do so? That he has not time for thought is an objection it is now sought to remove from his path, and if we can release the stranglehold of the "practical man" from his education and systematize his training there will be no difficulty in doing so. There are few students who would not be the better for at least a leaven of theoretical education, even if this did involve some small contact with metaphysics, of which I have not the superstitious dread shared by your correspondents.—I am, etc.,

### Character and Personality in the Medical Student

SIR,—I am instructed by the Committee of the St. Mary's Hospital Students' Union to write with reference to certain allegations made against the modern medical student in your columns (May 27, p. 729). Dr. E. D. Broster asks: "How can it be wondered at if the medical schools are crowded with men with brains but no character, with precepts but no principles? Decent living, refinement of speech and of conduct, love of poetry or the arts of good conversation, of wisdom, of learning—all these have been at a discount and have even been scoffed at in the physical and mental squalor of the years between the wars." In the majority of the great medical schools to-day there exist thriving societies for the advancement and study of these very arts and refinements. To name but a few: there are the medical societies, where many and varied subjects are lectured on and discussed; dramatic societies, where good plays are read and acted and dramatic art and literature considered in many of its aspects; musical societies, where great musicians of our time come to play and discuss good music. Furthermore—and this is important—in most schools these societies have arisen as an expression of a spontaneous desire of the students themselves.

How can it be said, then, that a love of these arts and of the good conversation that is part of them does not exist? And who would deny that character and principles and decent living are born or kept alive by the British love of sport, so well seen in the medical schools to-day? In the future these activities may well be extended and widened in their scope and receive a greater measure of official encouragement, in order that the students' general education may profit thereby; but to deny that these things exist at the present is surely idle.—I am, etc.,

DONALD BROWN,

Hon. Sec., St. Mary's Hospital Students' Union, W.2.

## Obituary

### JUDSON S. BURY, M.D., F.R.C.P.

Dr. Judson Bury, consulting physician to the Manchester Royal Infirmary, died at Chinley, Derbyshire, on June 10, aged 92. He had long retired from active practice, but was president of the Section of Neurology and Psychological Medicine at the Annual Meeting of the B.M.A. in Manchester in 1929.

Judson Sykes Bury was born at Salford the son of Peter Bury. He was educated at Amersham Hall, Reading, at Owens College, Manchester, and at University College Hospital, London. In 1877 he took the M.R.C.S. and the M.B., B.S. of London University, proceeding M.D. two years later, after holding resident posts at U.C.H. He then returned to Manchester, where, after a year as senior resident medical officer at the Children's Hospital, Pendlebury, he engaged in general practice and began his long connexion with the Royal Infirmary as non-resident medical registrar in 1885. He became assistant honorary physician in 1899, and remained on the active staff of the Royal Infirmary till 1912, when he reached the age limit. He was a very good teacher, clear and precise, but best on neurological subjects, and he wrote with an excellently lucid pen. He was well read in general literature, and introduced such knowledge with interesting effect into his professional papers. In 1893 he published a *Treatise on Peripheral Neuritis*, comprising a series of observations by James Ross, which Ross had intended to print as a complete monograph. On Ross's death at the age of 55 it was left to Bury to carry out the intention as fully as he could. The first half of the book was written from views expressed by word of mouth to him by Ross; but the rest was his own except the section on diabetic neuritis written by R. T. Williamson. Judson Bury also published in 1894 *Clinical Medicine*, a manual for the use of students and junior practitioners; it met with a good response and a third edition appeared in 1912, written jointly with Albert Ramsbottom, his junior colleague at the Manchester Royal Infirmary. In his *Diseases of the Nervous System* (1912) Bury adopted a clinical classification which he had found the most useful to the student. His method was to give a description of the chief neuronic systems, and then illustrate the various forms of paralysis and other nervous symptoms in relation to lesions of the corresponding neurons. He also wrote an article on peripheral neuritis in 1899 for *Allbutt's System of Medicine*. An interesting section of that article is the reference to the epidemic of neuritis caused by arsenical impurity in the beer supplied in the Manchester and Salford districts by a firm of brewers, the cause of which was discovered by E. S. Reynolds.

Judson Bury was elected a Fellow of the Royal College of Physicians of London in 1894 and delivered the Bradshaw Lecture before it in 1901, his subject being "Diagnosis in Relation to Disorders of the Nervous System." He examined in medicine for the College in 1911-15. He took his full share of honours in local scientific work, being president in turn of the Pathological Society and the Medical Society of Manchester, and of the Association of Physicians when it met in that city. He was professor of clinical medicine in Manchester University in 1911-12, and he edited the *Manchester Medical Chronicle* from those years until the disturbances caused by the last war ended his career. During 1914-18 he served with the rank of major, R.A.M.C., and did good work on medical boards in Manchester and Warrington.

Four years ago his friends and colleagues presented him with a book containing selected addresses and papers by him printed in Manchester between 1896 and 1939. Judson Bury bore his octogenarian years very well, never looking his age, his hair and beard scarcely silvering. He was a golfer and had been president of the local medical golf society.

### GEORGE WAUGH SCOTT, O.B.E., M.D.

George Waugh Scott was taken ill at the cottage of one of his country patients on June 6; he died a few hours later at his home in Malvern Links at the age of 61. After qualifying at Glasgow University in 1907 and serving as senior house-surgeon at Greenock Infirmary he became medical officer to

the Kamuning, Heawood, Changhat Salak, and Other Estates Hospitals Association, spending the bulk of his professional life in medical practice in Malaya, where his interests were particularly related to tropical medicine and epidemiology.

Since he came to Malvern in 1937 (writes a colleague) he has never rested on his oars; the outbreak of war saw him anxious to help his country, and he offered his services for the East again or wherever they might be required. He was asked to get the Malvern first-aid post going in 1939, and one of the most efficient posts with a happy staff resulted in record time. He made but one stipulation—that he should not be paid for this work; all his staff were unpaid volunteers and he must be treated similarly. In the brief but strenuous years he had resided in Worcestershire the character of the man "always to give of his best" was soon recognized by his patients, so that he gained their confidence and affection in a remarkable way. He was deservedly popular with all practitioners because he was always willing to help in any way and was a delightful companion. At the time of his death he was chairman-elect of the Worcester and Bromsgrove Division of the B.M.A., and in previous years had served on the council and as president of the Malaya Branch. He was a Fellow of the Royal Society of Tropical Medicine and the first president of the Vigornian Clinical Society. He showed that it was possible for one busy in general practice to keep abreast of the times, and to participate actively in hospital clinical meetings. These he seldom missed, nor did he fail to promote in them a lively discussion and an atmosphere of friendliness. He carried his Scottish individuality with him and radiated charm. More than one person had been heard to say that his companionship would go far to mitigate the disadvantage of life in the Far East. He is survived by his wife and his son Gavin, who continues in the practice.

T. S. M. writes: Waugh Scott will be mourned by many friends in this country, and by others in the Changi Concentration Camp at Singapore. He was truly a pioneer, and worked in Malaya from 1908 to 1936. His first tour of service was spent on a "jungle-locked" tin mine, in medical charge of some thousands of Asiatics, with only river and sea communications to Singapore. Later he settled in Perak, and became the medical officer for many rubber estates, certain public works, besides engaging in private practice. He was a sound general practitioner, and also an expert in the prevention of malaria and other tropical conditions. Many a poor Asiatic blesses his name, the wealthy companies appreciated his services and advice, and the Government acknowledged his welfare and public work by granting him the O.B.E. During a busy medical career he engaged in many aspects of public life, was a good churchman, president of the local B.M.A. and a member of most central medical and welfare bodies. In public he was a clear, thoughtful, and fearless speaker not always to his own advantage.

## The Services

Surg. Cmdr. G. M. Tanner and Surg. Lieut.-Cmdr. H. E. Holling, R.N.V.R., have been awarded the R.N.V.R. Officers' Decoration.

Col. (Temp. Brig.) E. A. Sutton, C.B.E., M.C., late R.A.M.C., to be a D.M.S., with the acting rank of Major-Gen.

Wing Cmdr. C. A. Rumball, R.A.F., was appointed O.B.E. (Military Division) in the Birthday Honours List published on June 8. This name was omitted from the list of medical honours published in the *Journal* of June 17 (p. 823).

Acting Wing Cmdr. C. C. Barker, R.A.F., has been awarded the A.F.C.

Fl. Lieut. G. D. Graham, M.B.E., R.A.F.V.R., has been awarded the D.S.O. in recognition of distinguished services in air operations.

### CASUALTIES IN THE MEDICAL SERVICES

*Wounded*.—War Subs. Capt. C. Cronin and A. D. Parsons, M.C., R.A.M.C.

*Killed*.—Major T. P. Ward, R.A.M.C.

*Died*.—Major V. H. Sarland, R.A.M.C.; War Subs. Capt. C. W. Williams, R.A.M.C.

### DEATHS IN THE SERVICES

Col. EDWIN THOMAS FAIRWEATHER BIRRELL, C.B., C.M.G., died on May 29 at Penicuik, Midlothian, at the age of 80. He was educated at Trinity College, Glenalmond, and Edinburgh University, where he graduated with the M.B. in 1895. He entered the Army Medical Service in the following year and reached the rank of colonel in 1917. During the Balkan war of 1912-13 he served as British Red Cross Society Commissioner for Bulgaria and received several foreign orders. During the war of 1914-18 he served at the headquarters of the British Expeditionary Force, and later with the British Salonika Force and with the British Military Mission to South Russia. He received the C.M.G. in 1915 and the C.B. in 1917. He retired in 1923 and was recently serving in the Home Guard.

## Universities and Colleges

### UNIVERSITY OF SHEFFIELD

On the recommendation of Senate the Council of the University has elected Mr. R. St. Leger Brockman, M.Chir., F.R.C.S., to the chair of surgery. Prof. Brockman served from 1914 to 1919 as a surgeon in the Royal Navy, after an undergraduate course of distinction at Cambridge and St. Bartholomew's Hospital. After the war he first went to Sheffield as a resident surgical officer at the Royal Infirmary; then followed a period in London as chief assistant at Bart's; after which he returned to Sheffield, where he has been an honorary surgeon at the Royal Infirmary, consultant to the City General Hospital, and lecturer at the University.

### ROYAL COLLEGE OF PHYSICIANS OF IRELAND

At a meeting of the President and Fellows of the Royal College of Physicians of Ireland held on June 2 the following were admitted:

As Fellows: Agnes Savill (*in absentia*), S. Simms, C. F. McConn, R. C. Sutton (*in absentia*), T. D. O'C. Donelan, E. B. McEntee, J. G. Gallagher, and W. J. E. Jessop.  
As Members: M. J. O'Malley and M. D. Hickey.

### ROYAL COLLEGE OF SURGEONS IN IRELAND

#### BOXWELL MEMORIAL

The teaching staff of the Schools of Surgery, Royal College of Surgeons in Ireland, has decided to institute a memorial to the late Prof. William Boxwell, who occupied the chair of pathology from 1916 to 1943. All Fellows and Licentiates of the College, and all other medical or non-medical persons who wish to associate themselves with this effort, are asked to subscribe to the memorial fund which is being formed. The fund will be devoted to providing some additions to the Department of Pathology which will further the study of that subject, and it is hoped that the appeal will meet with a generous response. Subscriptions should be sent to Prof. W. N. Rae, Sc.D., Registrar, Royal College of Surgeons in Ireland, Stephen's Green, Dublin.

## Medical Notes in Parliament

### Opium for Straits Settlements

During the debate on colonial administration on June 6 Mr. W. W. ASTOR expressed regret at the announcement of the Colonial Office that they would not allow opium in any form to return to the Straits Settlements. This decision would have the opposite effect to that desired by the Colonial Secretary, because it was quite certain that drug addiction would be far worse since the Japanese had been there. If opium were cut off entirely, with these large numbers of addicts there would be a tremendous black market, and smuggling and law evasion, bringing in drugs in much more dangerous forms, such as cocaine and heroin. This would lead to a worse drug problem, which would have to be tackled again.

### Vitamin D for Europe

On June 6 Viscount SUTDALE asked the Parliamentary Secretary to the Ministry of Economic Warfare in what quantities vitamin D was now being imported into German-occupied countries. Mr. G. H. HALL, who replied, said that the Government agreed to the dispatch of ten kilogrammes of vitamin D in December, 1943, and again in March this year. These twenty kilogrammes were for distribution to children in Belgium, France, Holland, Yugoslavia, and Poland. In addition we agreed, in October, 1943, to let one kilogramme go to Belgium, and last April a quarter of a kilogramme was sent for distribution in the Channel Islands. Before a concession was made in regard to vitamin D, none was imported with our consent into any part of enemy-occupied Europe except Greece, where all the demands of the Neutral Commission had been met.

### Voluntary Hospitals in an N.H.S.

Mr. WILLINK told Dr. Russell Thomas on June 8 that he could not then say how frequently routine and special inspections of voluntary hospitals participating in a national health scheme would take place. Details of the arrangements for inspections were matters to be considered at a later stage. Mr. Willink further informed Dr. Thomas that he had not estimated what average proportion the Exchequer grant and the payments of joint local authorities towards the cost of maintenance and treatment of patients would be to the total

cost of maintenance and treatment of patients in voluntary hospitals participating in a national health scheme. In the White Paper it was contemplated that, in the hospitals' interests, the aggregate of the central and local payments would be such as still to leave an opportunity for voluntary support. How this could best be arranged remained for discussion with the hospitals' representatives. The British Hospitals Association seemed to think that an opportunity for voluntary support was desirable.

## Medical News

Next year will be the bicentenary of the foundation of the world-famous Lying-in Hospital, Dublin, more usually known as the Rotunda Hospital. It has been decided that, on account of war conditions, it would be impossible to commemorate this date in a fitting manner in 1945, and it is proposed to hold in July, 1947, under the auspices of the Rotunda Hospital, a Congress of Obstetrics and Gynaecology in Dublin, which it is hoped that world conditions by then will allow to be of an international nature.

Prof. F. A. E. Crew of the University of Edinburgh will give a lecture under the auspices of the Polish Medical Association in the United Kingdom on "New Problems of Social Medicine," on Tuesday, June 27, at 5 p.m., at B.M.A. House, Tavistock Square, W.C. Visitors will be welcome. The lecture will be followed by a discussion.

The fourteenth annual general meeting of the Paddington Medical Society will be held on Tuesday, June 27, at 9 p.m. in the Board Room of St. Mary's Hospital, W. The title of Dr. Z. Green's presidential address is "Medicine in the Post-War Era."

A meeting of the Nutrition Panel of the Society of Chemical Industry will be held at 2.30 in the rooms of the Chemical Society, Burlington House, W., on Tuesday, June 27, when a series of four papers will be presented on "The Taste and Quality of Food in Relation to Nutrition" by Prof. H. Hartridge, Dr. G. W. Scott Blair, Dr. D. R. Davis, and Mr. R. R. Plowman.

The annual general meeting of the Fever Hospital Medical Service Group of the Society of Medical Officers of Health will be held at Tavistock House, Tavistock Square, London, W.C.1, on Friday, June 30, at 3 p.m. The subject for discussion will be penicillin, and the principal speakers will be Sir A. Fleming ("The Penicillin Content of Blood following Administration by Various Routes") and Dr. A. Dolphin ("Penicillin in the Treatment of Septicæmia and Meningitis").

The Lord Mayor paid an official visit on June 5 to the London Chest Hospital, Victoria Park, E., and before touring the wards inspected plans for rebuilding the hospital, which suffered severe damage during an air raid. The plans provide for a modern building with greatly increased accommodation.

The Oxford Ophthalmological Congress, which was to have been held in July, has been postponed. It is hoped it may be possible to arrange a meeting later in the year.

The meeting of the School Medical Service Group of the Society of Medical Officers of Health to have been held on July 21 has been postponed until further notice. The President of the Board of Education has promised to offer a date for his address to the Group as soon as circumstances permit.

Mr. F. G. Wells, of Hanwell, has been elected president of the Pharmaceutical Society of Great Britain. Mr. Wells is vice-chairman of the Middlesex Pharmaceutical Committee.

## EPIDEMIOLOGICAL NOTES

### Discussion of Table

In *England and Wales* the only infectious disease that increased markedly in incidence was measles, with 96 more notifications than last week. Notifications of the other infectious diseases decreased by the following amounts: scarlet fever 374, whooping-cough 154, dysentery 87, diphtheria 36.

Diphtheria notifications fell to the lowest weekly total yet recorded. This disease is relatively more prevalent in the north than in the south, and 41% of the total cases were notified in the counties of Yorks West Riding, Lancashire, Durham, and Northumberland, where 70, 69, 34, and 30 cases respectively were recorded. The decline in scarlet fever was general, and the number of notifications was the smallest for over one year. In Lancashire, Warwickshire, and Yorks West Riding whooping-cough notifications fell by 65, 40, and 37 respectively. In London the incidence of whooping-cough rose by 42. The largest increases in measles were in London 54 and Lancashire 47, while the largest fall was in Durham 30.

860 JUNE 24, 1944

## EPIDEMIOLOGY SECTION

Dysentery notifications numbered 178, this total being, with one exception, the lowest for seventeen weeks. The highest returns were Lancashire 33, London 24, Warwickshire 18, Glamorganshire 17, Derbyshire 13, Essex 13.

In Scotland there were 85 more cases of measles than last week, 78 of acute primary pneumonia, and 60 of whooping-cough. The rise in the incidence of pneumonia was general throughout the country, but measles and whooping-cough were prevalent mainly in Glasgow, where the cases were 68 and 35 respectively more than last week. Glasgow had 24 cases of dysentery, Lanark County 23, and Edinburgh 14; the total for the country rose by 7.

In Eire the notifications of measles dropped from 260 to 105. For the third week a case of typhus was notified in Roscommon, Castlereagh R.D.

In Northern Ireland there was a slight rise in the notifications of measles and scarlet fever. 40 of the 42 cases of measles and 29 of the 60 cases of scarlet fever were reported from Belfast C.B.

## Tuberculosis

The mortality from respiratory tuberculosis has fallen during the past two years after rising during the first war years. The female deaths in England and Wales were fewer in 1942 and 1943 than in the immediate pre-war years, but the male deaths were at a slightly higher level in 1942 than in 1938-9. In Scotland both sexes had a higher mortality in 1942-3 than in the pre-war years. Deaths from non-pulmonary tuberculosis in England and Wales have fallen to pre-war level, but they remain above the pre-war total in the notifications of tuberculosis since the outbreak of war. The data for 1938-43 are:

## England and Wales

Year	Deaths						Total
	Pulmonary			Non-pulmonary			
	Male	Female	Total	Male	Female		
1938	12,445	8,837	21,282	2,261	1,996	4,257

NOTES

Figures for 1943 are provisional only. Comparison of 1943 with those available.

## NOTES

Table for England and Wales.—The figures for 1943 are provisional only; separate figures for males and females are not yet available. Comparison of the deaths from pulmonary tuberculosis by age groups in 1943 with those in 1939 shows that increases occurred among children under 15 and among men at each age group over 35, whereas decreases occurred among women of each age group.

Table for Scotland.—Age groups specially affected by recent increases in pulmonary tuberculosis are: under 5 (M. and F.); 10 to 15 (F.); 15 to 25 (M. and F.); and 25 to 35 (M. and F.). There are no age groups specially affected by increases in non-pulmonary tuberculosis.

## Week Ending June 10

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,428, whooping-cough 2,473, diphtheria 470, measles 3,078, acute pneumonia 738, cerebrospinal fever 66, dysentery 181, paratyphoid 3, typhoid 1.

## INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended June 7.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) Scotland, (c) Eire, (d) Northern Ireland (administrative county), (e) The 16 principal towns in Scotland, (f) The 13 principal towns in Eire, (g) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notified no return available.

\* Includes primary form for England and Wales, and Eire, county, and Northern Ireland.

† Includes puerperal fever for England and Wales and Eire.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

## Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEGRAMS: EUSTON 2111. TELEGRAMS: Aetiology Writers. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the British Medical Journal alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: Articulate Western, London.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association, TELEPHONE: EUSTON 2111. TELEGRAMS: Medica Sec Western, London.

B.M.A. SCOTTISH OFFICE: 7, Drumchough Gardens, Edinburgh.

### ANY QUESTIONS?

#### Aetiology of Bronchiectasis

**Q.**—In reply to a query on the subject of bronchiectasis (Dec. 11, p. 771) it was stated that it was questionable whether inflammatory changes could be considered the primary cause of the condition. Could you inform me what alternative views are held regarding its aetiology? In my student days some 40 years ago bronchiectasis, a morbid condition obtrusively recognizable without recourse to radiography, was almost a rarity, but soon afterwards suddenly became common throughout the world.

**A.**—Your correspondent appears to have read into this answer rather more than is justified. I think that the distinction which was drawn was between pathological states rather than causes. There is, however, much controversy about the basic cause of bronchiectasis. There are two main theories: (1) that the infection of the bronchi is the primary cause and that collapse or consolidation of the lung is an adjunct or secondary effect; and (2) that collapse of part or the whole of a lobe produces a condition of dilatation which is made permanent and symptom-producing by subsequent infection. The evidence is discussed very fully in *Bronchiectasis* by Lisa and Rosenblatt (Oxford Medical Press, 1943), which is in the B.M.A. library. The very great apparent increase in the incidence of the disease is due to the fact that before the introduction of bronchography with lipiodol only very advanced cases could be diagnosed.

#### Some Facts about Dysentery

**Q.**—It was stated in your leader entitled "An Increase in Diarrhoeal Disease" (Jan. 29, 1944, p. 155) that there had been a big increase in the notifications of dysentery, and I see that the notification figure in the weekly epidemiological table shows no tendency to fall. Presumably in summer months it may even show a tendency to rise. Would it be possible to answer briefly the six questions I send?

**A.**—1. What is the usual mode of spread? Infectivity is high and the organism may be spread in a variety of ways: (a) from case to case, as when an infected person, after using the lavatory, soils the seat or the handle of the flushing cistern; or, without washing his hands, proceeds to contaminate food, cutlery, drinking vessels, etc.; (b) as an explosive outbreak when an infected food-handler contaminates milk or milk products or other prepared foods; (c) contamination of food by flies.

2. Is there an animal reservoir of infection? No: except that infected flies may carry the organism for 24 hours.

3. How is infection maintained in the community? (a) By the missed mild case. (b) By the convalescent carrier, whom modern cultural methods have shown to be very common and who may continue to excrete the organism for weeks after he is clinically well. (c) By the healthy contact carrier, of whom there is always a fair proportion in any outbreak.

4. What are the symptoms and duration of the mild form likely to be missed? Both Flexner and Sonne infections occur in mild atypical form without blood or mucus in the stools; the symptoms may be diarrhoea or relaxed stools for one day only.

5. What is the treatment—dietetic, drug, isolation? (a) Light restricted diet—e.g., predigested milk foods—until the diarrhoea ceases. (b) The safest drug is sulphaguanidine, 4–6 g. daily for a child, and 9–12 for an adult, given 4-hourly during the day. Begin treatment as early as possible and reduce to half doses after 4 days; continue for 3 more days. Good results are also obtained with sulphydrydine or sulphathiazole. Adequate fluids must be given. (c) Isolation at home or in hospital is essential where there are other, particularly younger, children in the household.

6. If the disease is generally mild, is the use of sulphonamides justifiable? In mild infections sulphonamide therapy is required to obtain bacteriological cure as early as possible and so minimize the risk of spread. Sulphaguanidine will do this in Flexner infections;

sulphydrydine or sulphathiazole is more effective in Sonne infections. The earlier treatment is begun, the better the chance of bacteriological cure. Intimate family contacts may be protected by small daily doses (2–3 g.) of sulphaguanidine.

#### Still More about Threadworms

**Q.**—Some textbooks state that *Enterobius vermicularis* does not multiply in the intestine, and that it is necessary for the eggs containing embryos to be swallowed to produce a fresh crop of adult worms. If this is true and reinfection is prevented, it is difficult to understand why a spontaneous cure should not occur, whereas it is stated in an answer to a question in the *Journal* of March 25 last (p. 445) that "treatment is proverbially unsatisfactory."

**A.**—The difficulty is to prevent reinfection. The gravid females crawl out of the anus at night and lay their eggs in the peri-anal region, the larva within the egg becoming infective within 12 hours. The migration of the females causes an intense itching, which invariably leads to scratching of the infected region, often during sleep; as a result the fingers become contaminated with the eggs, which are afterwards carried to the mouth and swallowed.

#### Operation for Acute Appendicitis

**Q.**—Why do some surgeons nowadays appear to make a practice of never operating upon cases of acute appendicitis? From a pathological point of view it seems all wrong. There must be a large number of people who have had an attack who still have their infected appendix inside them. Is it a passing phase to "sit on" acute cases, or have we returned to pre-Edwardian days? The surgeons who do this would probably not "sit on" an acute mastoid.

**A.**—Many cases of acute appendicitis will resolve if the intestine is put completely at rest. Some, however, will develop complications; and, since nobody can tell in the early stages of the disease to which group the case may belong, very few surgeons make a practice of never operating upon acute appendicitis.

From the pathological point of view it is interesting to note that resolution, even after abscess formation, means a return to a state so closely approximating to the normal that within a few weeks (on the average about six weeks) the caecum and appendix appear healthy at laparotomy. Furthermore, there is little resemblance between this condition and mastoiditis, for in any bone infection there is a risk of spreading phlebitis, which is fortunately such an uncommon event in appendicitis.

The conservative treatment of carefully selected cases of acute appendicitis cannot be regarded as a passing phase; and to suggest that it may be a return to the age when appendicitis was little understood shows a lack of appreciation of the modern conception of the response of the body to acute infection.

#### Anaesthesia for Torn Perineum

**Q.**—We have been told a good deal lately of the danger of using spinal anaesthesia in labour. Does the danger still exist if a low spinal anaesthetic is given for sewing up a torn perineum?

**A.**—General anaesthesia is unnecessary for the repair of small perineal tears. Local anaesthesia in the form of 1% procaine is simple, safe, and effective. For extensive tears involving the anal sphincter a general anaesthetic is usually required. In view of the circulatory adjustments that follow the completion of the third stage of labour, anaesthesia (such as spinal) that lowers the blood pressure should be avoided; furthermore the risk of meningitis after lumbar puncture has always to be considered.

#### Risk of Embolism in Labour

**Q.**—A woman of 41 is expecting her first child at the end of July. She is very stout; her blood pressure varies from 110/80 to 130/80. She has marked varicose veins on both legs. She has had headaches of a migraine type (severe and frequent attacks) before and at the beginning of her pregnancy, but not so many recently. Her own mother died from embolism after confinement. (1) Would heparin be indicated to prevent embolism after her confinement, or would its administration endanger her by interfering with the necessary clotting at the site of the placenta, as it extends the coagulation time? (2) What would the dosage and mode of administration be, and when would treatment have to begin? Is there any other prophylactic treatment for such a case?

**A.**—This patient would not appear to be an ideal obstetrical type. Her blood pressure, however, is reassuring. The present position in regard to the use of heparin in this type of case is not sufficiently clear to permit its use to be freely advocated. There are dangers, and if the treatment were to be given it should be done in a well-equipped institution with adequate pathological facilities, where daily progress could be supervised by specialists. An older but better line of treatment would be to concentrate during the ante-natal period on raising the haemoglobin to its maximum level; for anaemia would, of course, be a predisposing factor in bringing about subse-

quent thrombosis and embolism. Once the child is delivered the mother must be encouraged to move about actively in bed, and even if an episiotomy is performed or a tear is sustained she should be encouraged to move her legs and thus maintain adequate circulation. The use of an efficient masseuse to supervise active movement and massage would be a great help. A factor in this case which should not be overlooked in a primigravida of 41 is the natural anxiety she must have in view of the nature of her mother's death. Encouragement throughout her ante-natal period will do a great deal to lessen her fears and, as a result, the chance of inertia occurring. This is the more necessary as any prolongation of her labour or excessive interference will be likelier to precipitate a subsequent thrombosis.

#### Grenz Rays

Q.—Some time ago, in reply to a question on leucoderma, it was stated that Grenz rays sometimes proved beneficial. I have made inquiries among colleagues (including radiologists), but have been unable to obtain any information about them, or about anyone with the necessary apparatus and skill.

A.—Very low voltage (or infra-Roentgen) rays were first studied by Schultz in 1911 in the treatment of some skin diseases. Their use was developed and popularized by Bucky (Grenz Ray Therapy, trans. 1929). Grenz rays are nearer x rays than ultra-violet; their wavelength is about 2 Angström (glass of a low density) to allow passage has a lithium glass window (absorbed in the epidermis, so of the rays. Almost all the rays are absorbed in the epidermis, so local applications may be useful in superficial dermatoses, especially when any deeper effect is to be avoided, as in the scrotum or eyelids. Bucky and others have also reported, by general trunk irradiation, distant effects on many diseases in which an endocrine or autonomic nervous system factor may be involved, as in asthma, arthritis, angioneurotic oedema, urticaria, and allergic dermatitis. These observations require confirmation. Many of the complaints listed have sometimes responded also to other forms of irradiation, as ultra-violet and small doses of x rays to the trunk, in continued series of sessions, with frequent blood counts as a check. Bucky's results, if confirmed, support the theory that the skin acts in part as an endocrine gland, and they increase the already wide, but largely unexplored, field of indirect radiotherapy, which has its greatest scope of accepted usefulness in the results of heliotherapy or ultra-violet light therapy (general) in tuberculosis, when associated with other hygienic measures. Bucky's papers in the *Medical Record* (1935, 142, 71, 109, and 165) summarize the general effects of Grenz rays in alopecia, vitiligo, and other conditions, as well as those above mentioned.

#### B.C.G. Vaccine

Q.—What is B.C.G. vaccine? Is it obtainable at the present time commercially? Is it likely to be of use for immunizing a native population in the Tropics which is being attacked by tuberculosis? You tell me where detailed information for its use can be found?

A.—A suspension of living tubercle bacilli of the strain known Calmette-Guérin bacillus, which by prolonged artificial cultivation in unfavourable media has been rendered almost completely avirulent and incapable of causing progressive disease even in the highly susceptible guinea-pig. It has been administered by the mouth to infants, mainly in France, and by subcutaneous injection to both children and adults. There is sound experimental evidence that it will increase the resistance of guinea-pigs and calves to infection with virulent tubercle bacilli, and some clinical evidence of protection in human beings, notably among nurses in Scandinavia. The question is referred to the *Journal* of Dec. 4, 1943, which contains a report of a discussion on this subject at a meeting of the Tuberculosis Association, and editorial comments thereon. The numerous original papers of French, Scandinavian, and American authors should be consulted for details. The immunization of a susceptible native population exposed to infection is decidedly a proper field for employing B.C.G. vaccine. It is not obtainable commercially in England, and should in any case preferably be prepared in the country in which it is to be used, since, like all preparations of living micro-organisms, it has a short effective life.

#### Sterilization of Syringes

Q.—What is the best solution to use for sterilizing hypodermic syringes and needles and keeping them sterile in spirit-proof cases? The ideal solution for practical purposes would (1) sterilize in about 5 minutes (2) maintain sterility for several days or weeks without spoiling or corroding. Would a 2% solution of dettol in methylated spirit fulfil these objects?

A.—We know of no evidence that any feasible chemical method can be relied on for disinfecting a contaminated syringe. Any syringe which has been used for a septic purpose should always be sterilized by heat. On the other hand, a syringe kept only for aseptic purposes, such as the injection of sterile medicaments through normal skin, should not require repeated disinfection by an infallible method in the ordinary circumstances of careful use. If safety is

to be combined with reasonable convenience, a distinction must be made between different types of use, sterilization by heat being always regarded as the only perfectly reliable method, and imperatively called for when contamination is known or suspected, or when the risk, even if remote, is great, as in mass inoculation.

#### Mode of Action of Aspirin

Q.—Would you give me a summary of the mode of action of aspirin?

A.—The full chemical explanation of the action of aspirin is still unknown, but the following facts have been established. Aspirin lowers the temperature in fever by acting on the centres in the hypothalamus which regulate heat loss. The temperature fall because of increased heat loss, due to sweating and to dilatation of the skin vessels. These changes do not occur if the temperature is normal. Aspirin causes a small fall of the metabolic rate, but does not lower the temperature of normal persons unless toxic doses are used. Aspirin also has a mild analgesic effect due to an action on the brain, and, like other derivatives of salicylic acid, it reduces the swelling of the joints, in rheumatic fever. Very large doses cause restlessness, delirium, and convulsions, followed by coma and death, but absorption is slow and lives can be saved by washing out the stomach. A few persons have an idiosyncrasy for aspirin, so that comparatively small doses cause an allergic response in the form of asthma, vasodilatation, or urticaria.

## LETTERS, NOTES, ETC.

### The Tavistock Clinic

The Tavistock Clinic (Institute of Medical Psychology), at present housed at Hampstead, reports a year of as great activity as a depleted staff will permit. Only in one previous year in the Clinic's history was the number of those applying for advice and treatment as great as in 1943. In the adult department the types of complaint which have brought the patients to seek advice have shown no marked changes, but whatever the specific condition, depression is usually present to some extent. This is thought to be the result of the cumulative effect of fatigue, frustration, and exhaustion. While it is only for a minority that wartime conditions amount to a real burden affecting health, the margin for many of the remainder is narrowing, and any additional strain may be felt to be intolerable. The number of adult attendances in 1943 was 6,410, and of child attendances 3,807, and as each interview lasts normally an hour, the strain on the small staff can be imagined. Intelligence tests have been carried out on the children who for various reasons have been referred to the Clinic. Half of them have been found to be of average ability, compared with approximately 75% in a normal sample of the population; 30% of the children were found to be above the average. This confirms the belief that psychological problems arise to a greater extent in those of unusually good or unusually poor ability, with, in the Tavistock Clinic experience, the balance weighted slightly towards the higher level.

### Vomiting of Pregnancy

Dr. W. I. HARDY (Vibthwaite, Nr. Ulverston) writes: I have read with interest the letters of Drs. Calvert and Edwards regarding the aetiology and treatment of vomiting of pregnancy. Dr. Calvert (June 3, p. 772) supports the theory that the digestive disturbances of pregnancy may be due to the high blood level of progesterone. I have noted that injections of progesterone—given to assist or prevent abortion—may apparently initiate nausea and vomiting in patients who had not yet developed this symptom. This may, of course, be a coincidence, as they were given during the first three months. Nausea and vomiting if previously present have become more severe for a short period following the progesterone injections. Certainly injections of oestrin appear to benefit one-third to one-half of cases of indigestion in pregnancy. Unfortunately for the endocrine theory of causation of symptoms, these do not always respond to endocrine therapy.

### Fasciculating Muscles

As one reader has misunderstood a sentence in the answer to a question under the above heading in the *Journal* of June 10 (p. 801), other readers may have erred similarly. The sentence read as follows: "Although it is rare, the condition is well recognized by neurologists, to whom it is usually referred as amyotrophic lateral sclerosis." To make the matter explicit for the hurried reader, the second half of the sentence should perhaps have read, "... to whom it is usually referred with the wrong diagnosis of amyotrophic lateral sclerosis."

The shilling pamphlet entitled *A Reading List for Relief Workers* noticed on June 10 (p. 785) is not published by the Oxford University Press but by the Royal Institute of International Affairs, Chatham House, 10, St. James's Square, London, S.W.1.
